Foreword

In reading through the *Textbook of Pulmonary and Critical Care Medicine* edited by Professor SK Jindal of the Postgraduate Institute of Medical Education and Research, Chandigarh, my thoughts drifted to a recent best-selling book authored by Thomas Friedman, titled, *The World is Flat: A Brief History of the Twenty-first Century*. The author argues that the world is shrinking from a size small to a size tiny and this has been accompanied by a flattening of the playing field. The dynamic forces of recent globalization give a unique quality to our flat world today—the power of individuals to collaborate and compete globally. Using this 21st century power and the tools of the flat world, namely the personal computer, the fiberoptic cable, and modern publishing house software, Professor Jindal has fostered an outstanding collaboration among experts spanning several continents. He has also produced a practical, authoritative and comprehensive resource for students, physicians in training and seasoned clinicians alike, that rivals any standard textbook on this subject and can compete on equal footing with other educational tools.

However, as globalization flattens the playing field, and countries leap to industrialization, cultural beliefs, natural resources, climate and geography have slowed the pace of development in many parts of the world. Poverty leads to malnutrition, homelessness, lack of education, and poor access to health care. Overcrowded cities and rural underdevelopment are other challenges that impact health in the various parts of the world. Moreover, epidemics of HIV, drug abuse and smoking addiction take a greater toll on the population. Yes, the world is flat, but the terrain is filled with mountains and valleys and local problems demand local solutions. And these local problems need to be explored and presented with a scholarly perspective. The *Textbook of Pulmonary and Critical Care Medicine* has successfully incorporated these sociodemographic factors into the subject matter.

The text is well-written and the chapters are carefully referenced with subjects found in all traditional pulmonary and critical care textbooks, e.g. airway diseases, interstitial lung disease, pleural disease, pulmonary neoplasia, pulmonary infection, sleep and critical care. There are several nontraditional sections as well that are practical and especially helpful to the practicing physician. These include a section on the symptom approach to lung disease, an overview of the pharmacologic agents used to treat lung disease, and a comprehensive review of methods in lung diagnosis from the simple history and physical examination to the latest complex tools of interventional pulmonology. The textbook is especially unique because of the abundance of illustrations, flow charts and tables. Their clarity and at times simplicity make them especially valuable for the novice. There are many radiographic and pathologic reproductions that are especially helpful.

The textbook also offers a unique exposure to the problems in many parts of the world. Tuberculosis, the "number one" treatable condition has been extensively covered; and special topics such as multi-drug resistance, directly observed therapy, TB prevention, nonpharmacologic approaches and extapulmonary tuberculosis are particularly relevant. Many countries are facing a growing burden of noncommunicable respiratory diseases. They have become the second leading cause of death after injuries, and their impact on indirect costs such as loss of work and home productivity is enormous. These problems are addressed and measures of prevention such as smoking cessation are included. Other special challenges including topics such as indoor and outdoor air pollution, climate change, poisoning with pesticides, snakebite toxicity, pulmonary manifestations of tropical infections and industrial accidents such as the tragedy seen in Bhopal, Madhya Pradesh, with methyl isocyanate, have been well covered.

What is most impressive about this textbook is how comprehensive and practical it is for the reader. Topics range from the history of respiratory medicine to the approach to end-of-life issues with critically ill patients. It is hard to think of a topic that is missing. While this textbook will have a special appeal and value to the physicians of the South-Asian continent, clinicians around the globe will benefit from Professor Jindal's extensive efforts.

Sidney Braman MD FCCP
Former President ACCP
Rhode Island Hospital, 593 Eddy Street
Providence, RI 02903 USA

Preface

It was merely a quarter of a century ago when the specialty of Pulmonary Medicine was factually recognized as an important division of Medicine. Until then, the lung diseases were generally dismissed as tuberculosis, or nondescriptive pneumonias and infections. Most of the nontuberculous lung diseases remained either undiagnosed or unknown. Of course, several stalwarts of the sixties and seventies had clearly identified this deficiency and made efforts to define the pulmonary problems and plan their solutions.

It was in 1989 that the first independent, postdoctoral DM Fellowship Program in Pulmonary Medicine was started at Chandigarh. Subsequently, the program was expanded to include the Critical Care as an essential component of the DM training. In addition, there were several postgraduate MD and/or diploma courses in tuberculosis and chest diseases, and/or respiratory diseases at different medical colleges. Unfortunately, most of the postgraduate programs lacked in their curricula especially for nontuberculous diseases and other systemic disorders. Moreover, the on-hand training in diagnostic and treatment modalities had been highly inadequate in the postgraduate courses. It is rather enigmatic that we still continue to lack the dedicated thoracic surgery courses and texts in the various countries.

The increased importance and scope of respiratory and critical care medicine had also necessitated the need to develop the indigenous teaching and training materials including the texts with incorporation of local problems and possible solutions. Undeniably, the science is the same all over the world, but the experiences are different. Excellent texts and reference materials on the subject are available for long which continues to guide the students, the teachers and the practicing physicians. In the present literature, quite a few textbooks of pulmonary medicine have been published and continue to remain available. Ours is one more attempt in this direction to add to the existing literature on lung diseases available worldwide. This book contains contributions by approximately hundred international esteemed pulmonary medicine consultants and teachers.

There are, however, a few important additions in the present textbook. It is fairly comprehensive with contributions from several internationally eminent authors. It includes the basic principles as well as the recent advances related to different subjects. We have also attempted to incorporate allied clinical sciences relevant to the practice of the pulmonologist. A classical example is the critical care which forms an integral component of pulmonary medicine. It also incorporates tuberculosis, other pulmonary infections, environmental and occupational medicines, sleep disorders and general systemic diseases affecting the respiratory system in one or the other way. Although the critical care is relevant to most of the medical and surgical specialties, the pulmonologists have a more vested interest than other specialists. Assisted respiration which forms the core of most critical care lies in the primary domain of pulmonologists.

We have taken care not to forget the need to push forward and meet the goals of excellence in health care. The real test of merit of a book lies in its readership by the students and adoption of its recommendations in clinical practice. Hopefully, the material in the text will benefit a diverse category of people including internists, general physicians, pulmonologists, pediatricians, intensivists, anesthesiologists and others who need to handle patients with respiratory diseases and critical care.

SK Jindal

Acknowledgments

I was greatly encouraged by my friends and colleagues in the department and elsewhere across the world. Almost none had refused my request to participate in this venture and provided best of his/her inputs. I am especially indebted to my Associate Editors and the Section Editors who have put extra efforts to make each section as all-inclusive. Drs PS Shankar, VK Vijayan, R Guleria, SK Chhabra, George D'Souza, and Sundeep Salvi had taken a lot of load on their shoulders. Most importantly, the international contributors had taken a lot of pains to enrich the book, purely for academic and scientific investments. In particular, I am thankful to Drs Om P Sharma, Irwin S Richards, Sidney S Braman, Robert McCaffree, Kalplatha K Guntupalli, Pravin Mathur, Ruby Pawankar, Peter Barnes, Daniel Banks and Suhail Raoof who have not only contributed themselves but also helped in getting the best from many others.

My faculty colleagues, Drs D Behera, Dheeraj, Ashutosh, Ritesh and Navneet, Senior Residents and Pulmonary-Fellows had remained a constant source of assistance. I greatly pay my sincerest appreciation to all of them. Ms Manju Aggarwal, my Secretary had done a remarkable job of refining and typing the manuscripts. I also owe a great deal of gratitude to my wife Umesh and children who have borne with my being busy and helping me in sorting out difficult matters.

Nothing could have been accomplished without the efficient editing and publishing by M/s Jaypee Brothers Medical Publishers (P) Ltd, Delhi who have done an excellent job. Shri Jitendar P Vij, CEO, had taken his personal interest in this publication. Dr Naren Aggarwal and Dr Richa Saxena deserve my special thanks for coordinating the process of publication.

Contents

SECTION 1: HISTORY AND DEVELOPMENT

SK Jindal

1. **History of Respiratory Medicine** **3**
   FE Udwadia
   Introduction 3; The Discovery of Chemotherapy and Antibiotics 6

2. **Anatomy and Architecture: A Clinical Perspective** **9**
   SK Jindal
   Lung Anatomy and Morphology 9; Architecture of Lung Parenchyma 12; Blood Supply of Lungs 13; Lymphatic Drainage 14; Nerve Supply 15

3. **Lung Development** **18**
   Meenu Singh, Nidhi Anil, Amit Agarwal
   Introduction 18

4. **Genomics of Lung Diseases** **24**
   L Keith Scott
   Introduction 24; Genomics and Disease 24; Genomic Nomenclature and Investigational Tools 25

SECTION 2: RESPIRATORY PHYSIOLOGY

SK Chhabra

5. **Applied Respiratory Physics** **35**
   SK Jindal, VK Jindal
   Introduction 35; State of Matter 35; Physical Properties of Gases 36; The Gas Laws 38; Gas Solution and Tension 39; Vapors 39; Expression of Gas Volumes and Pressures 40; Flow of Gases 40

6. **Respiratory Function and Mechanics** **43**
   D Gupta, R Agarwal, Ashutosh N Aggarwal
   Introduction 43; Ventilation 44; Pulmonary Circulation 48; Diffusion 50; Ventilation-perfusion ($\dot{V}/\dot{Q}$) Relationships 51; Control of Ventilation 52

7. **Gas and Fluid Exchange in the Lung** **54**
   Marc Zelter
   Gas Exchange 54; Dead Space and Alveolar Gas 56; Transfer of Gas across the Alveolar Capillary Membrane 57; Gas Transport to and from the Periphery 58; Ventilation Perfusion Ratio 60; Fluid, Solutes and Protein Exchange in the Lung 64; Clinical Implications 71; Measurement of Extravascular Lung Water 72

8. **Tissue Oxygenation** **74**
   Puneet Malhotra, SK Jindal
   Introduction 74; Oxygen Delivery (DO_2) 74; Oxygen Consumption (VO_2) 76; Assessment of Tissue Oxygenation 78; Recent Developments 79

9. **Respiratory Physiology in Specific Physiological States** **81**
   Sunil K Chhabra, Mansi Gupta
   Introduction 81; Exercise 81; Pregnancy 84; High Altitude 86; Deep Diving 88

10. Mechanisms of Dyspnea in Respiratory Diseases **93**
Sunil K Chhabra, Ashima Anand
Introduction 93; Definitions 93; Perception: The Subjective Element in Dyspnea 94; Neural Pathways of Dyspnea 94; Pathophysiological Mechanisms of Dyspnea 97

11. Surfactant **107**
Gyanendra Agrawal, SK Jindal
Introduction 107; Composition of Lung Surfactant 107; Functions of Lung Surfactant 109; Surfactant Metabolism and Surfactant Film Formation 110; Disorders of Surfactant Metabolism 112; Conclusion 115

12. Respiratory Defenses and Immunology **118**
Padmavathi Ramaswamy, Padma Srikanth, Vijayalakshmi Thanasekaraan
Introduction 118; Particle Deposition in the Respiratory Tract 119; The Defense Mechanisms of Conducting Zone of the Airways 119; The Defense Mechanisms of Respiratory Zone of the Airways 124; Surfactant and Surfactant Protein A (Sp-A) 125; Respiratory Immune Mechanisms 126; Alveolar Macrophages 127; Impact of Bacteria and Viruses on Lung Immunology 130; HLA and Mycobacterial Diseases 131

SECTION 3: PHARMACOLOGICAL AGENTS

Nusrat Shafiq, Samir Malhotra

13. Antibacterial Drugs **135**
Nusrat Shafiq, Samir Malhotra
Introduction 135; Beta-lactams 135

14. Antiviral Drugs **155**
Nusrat Shafiq, Samir Malhotra
Introduction 155; Mechanism of Action of Antiviral Drugs 156

15. Antifungal Drugs **159**
J Whig, Bharti Mahajan, Rajesh Mahajan
Introduction 159; Specific Issues 166; Clinical Implications of the Antifungal Drugs 166

16. Anti-inflammatory Agents for Asthma **171**
Nusrat Shafiq, Samir Malhotra
Introduction 171; Corticosteroids 171; Dissociated Steroids 173; Mast Cell Stabilizers 176; Miscellaneous Drugs 177

17. Immunosuppressant Drugs **180**
Nusrat Shafiq, Samir Malhotra
Introduction 180; Glucocorticoids 180; Calcineurin Inhibitors 181; Antiproliferative/ Antimetabolic Drugs 182; Immunosuppressive Cytotoxic Drugs 183; Miscellaneous Immunosuppressants 184

SECTION 4: SYMPTOM-APPROACH TO RESPIRATORY DISEASE

Richard S Irwin

18. Cough in the Adult **189**
Scott E Kopec, Deirdre L Kathman, Richard S Irwin
Introduction 189; Epidemiology 189; Physiology 189; Pathophysiology 190; Benefits of Cough 190; Complications of Cough 190; Causes of Cough 191

19. Hemoptysis **204**
Andrés F Sosa, J Mark Madison, Paulo J Oliveira
Introduction 204; Anatomy 205; Etiology and Pathogenesis 205; Treatment 213

20. Dyspnea **222**

J Mark Madison, Richard S Irwin

Introduction 222; Physiology 222; Positional and Nocturnal Dyspnea 224; Evaluating Acute Dyspnea 224; Evaluating Chronic Dyspnea 225; Treatment 226

21. Wheeze and Respiratory Disease **229**

J Mark Madison, Richard S Irwin

Introduction 229; Physiology of Wheeze 229; History and Physical Examination 229; Pulmonary Function Testing 230; Differential Diagnosis for Wheezing 232; Approach to the Diagnosis of Wheeze 235; Treatment 235

SECTION 5: RESPIRATORY DIAGNOSIS

SK Jindal

22. History and Physical Examination **241**

PR Gupta

Introduction 241; History Taking 241; History of Previous Diagnosis and Treatment 244, The Physical Examination 244

23. Microbiological Approach to Respiratory Infections **251**

Pallab Ray

Upper Respiratory Tract Infections 251; Lower Respiratory Tract Infections 255

24. Systematic Approach to Interpretation of Plain Chest Radiographs **264**

D Behera

Introduction 264; Radiology and Imaging 264

25. Pulmonary Imaging: Systematic Approach to Interpretation of Computed Tomography of the Chest **296**

Rubal Patel, Rakesh Shah, Sabiha Raoof, Suhail Raoof

Introduction 296; Technical Aspects 296; Normal Components of the Pulmonary Parenchyma 297; Normal Lung Components of the Airways 305; Normal Lung Component of the Pulmonary Vasculature 309; Tracheobronchial Diseases 311; Parenchymal Diseases 314; Mediastinal Diseases 324; Miscellaneous 326

26A. Pulmonary Function Testing **331**

Ashutosh N Aggarwal

Introduction 331; Spirometry 331; Peak Expiratory Flow 336; Static Lung Volumes 336; Diffusing Capacity of Lungs 338; Exercise Testing 340; Other Tests 342

26B. Respiratory Muscle Function **346**

Randeep Guleria

Introduction 346; Respiratory Muscles—Basic Physiology 347; Evaluation of Respiratory Muscle Function 348

27. Respiratory Disability and Preoperative Evaluation **358**

Gyanendra Agrawal, D Gupta

Introduction 358; Evaluation of Respiratory Disability 358; Clinical Methods of Evaluating Impairment 358; Disease-specific Impairment Assessment 360; Disability Evaluation 361; Preoperative Evaluation of Respiratory System 361; Postoperative Pulmonary Complications 363; Preoperative Evaluation 365; Recommended Approach 368; Optimizing the Chance of a Successful Outcome 369

28. Arterial Blood Gases and Acid Base Balance **373**

Vinaya S Karkhanis, Jyotsna M Joshi

Introduction 373; Physiology of Gas Exchange 373; Physiology of Acid Base Balance 374; Arterial Blood Gas Analysis 378; Arterial Blood Gas Interpretation 380; Interpretation of Arterial Blood Gas 384; Pitfalls in Arterial Blood Gas Interpretation 385; Examples 385

29. Nuclear Imaging in Pulmonary Medicine **387**
BR Mittal, Sunil HV
Introduction 387; Pulmonary Anatomy and Physiology 387; Investigations 387

30. Role of Cytology in Lung Lesions **399**
Arvind Rajwanshi, Nalini Gupta
Cytological Techniques in Respiratory Cytology 399; Aspirations 402; Imprint Cytology 403; Endoscopic Ultrasonography Guided FNA and Endobronchial Ultrasound FNA 403; Inflammatory Diseases of the Lung 403; Neoplastic Lesions of the Lung 407

31. Bronchoscopy **418**
R Narasimhan, AR Gayathri
Introduction 418; Types of Bronchoscopy 418; Patient Preparation and Anesthesia 419; Diagnostic Bronchoscopy—Accessories 419; Indications for Diagnostic Bronchoscopy 420; Diagnostic Procedures 424; Therapeutic Bronchoscopy 425; Electronavigation Bronchoscopy 426; Safety Factors in Bronchoscopy 426; Complications of Bronchoscopy 427

32. Interventional Bronchoscopy **429**

40. Pulmonary Tuberculosis: Clinical Features and Diagnosis **539**
S Kashyap, Malay Sarkar
Introduction 539; Post Primary Pulmonary Tuberculosis 539; Symptoms and Signs 539; Tuberculosis in the Elderly 541; Miliary TB 541; HIV and TB 542; Pleural Effusion 542; Paradoxical Response 542; Physical Examinations 542; Diagnosis of Tuberculosis 543; Extrapulmonary Tuberculosis (EPTB) 549

41. Molecular Diagnosis of Tuberculosis **554**
Mamta Kalra, Indu Verma, Suman Laal
Introduction 554; Diagnosis of TB in Low-income Countries 554; Diagnosis of TB in High-income Countries 555; TB Diagnosis in HIV+ Individuals 556; Diagnosis of TB: Beyond Microscopy 556

42. Management of Tuberculosis **568**
D Behera
Chemotherapy of Tuberculosis 568; Rationale for Recommended Treatment 573; Regimens 573; Supervision of Chemotherapy 575

43. Antitubercular Drugs **578**
SK Katiyar, S Katiyar
Introduction 578; Isoniazid 579; Rifampicin 581; Streptomycin 583; Pyrazinamide 584; Ethambutol 585; Quinolones 586; Para-aminosalicylic Acid (PAS) 586; Ethionamide/Prothionamide 587; Cycloserine/Terizidone 587; Capreomycin 588; Thiacetazone 588; Group 5 Drugs 588; Clofazimine 589; Linezolid 589; Amoxicillin/Clavulanate 589; Imipenem/Cilastatin 589; Clarithromycin 589; High-dose Isoniazid 589

44. Historical and Non-pharmacological Management of Pulmonary Tuberculosis **594**
KB Gupta
Introduction 594; History 594; Ancient Drugs in the Treatment of Tuberculosis 595; Sanatorium Treatment 596; Surgery 598; Immunotherapy 599; Tuberculosis and Nutrition 600; Rehabilitation in Tuberculosis 602

45. Prevention of Tuberculosis **608**
Rajesh N Solanki, Ghanshyam B Borisagar, Jitendra A Sisodia
Introduction 608; Primordial Prevention 608; Primary Prevention 608; Secondary Prevention 612; Tertiary Prevention 615

46. BCG Vaccine **616**
PT James
Introduction 616; Complications of BCG Vaccination 619

47. Extrapulmonary Tuberculosis **622**
Ashok K Janmeja, Prasanta R Mohapatra
Introduction 622; Diagnosis 622; Lymph Node Tuberculosis 623; Pleural Effusion 625, Bone and Joint Tuberculosis 626; Central Nervous System Tuberculosis 628; Abdominal Tuberculosis 629; Genitourinary Tuberculosis 632; Skin Tuberculosis 633; Disseminated Miliary Tuberculosis 634; Pericardial Tuberculosis 636; Hepatic Tuberculosis 637

48. Multidrug-resistant Tuberculosis **641**
Surendra K Sharma, Ninoo George
Introduction 641; Epidemiology 641; Definition 642; Causes of Drug Resistance 642; Diagnosis of Drug-resistant TB 643; Management 644; Role of Immunotherapy 647; Resective Thoracic Surgery 648, Nutritional Support 648; Special Situations 648; Prevention of Nosocomial Transmission of MDR-TB 649; Financial Burden of MDR-TB 650; Cure Rates in MDR-TB and XDR-TB 651

49. Revised National Tuberculosis Control Programme in India—DOTS and DOTS Plus **656**
D Behera
Introduction 656; Revised National Tuberculosis Control Programme 657; Diagnosis of Pulmonary Tuberculosis 662; Ziehl-Neelsen Staining Procedure 663; Treatment 668; Management of Pediatric Tuberculosis Under RNTCP 674; Management of Extrapulmonary Tuberculosis 676; Management of Patients with HIV Infection and Tuberculosis 677; Recording and Reporting 680; Supervision, Monitoring and Evaluation 683; Training 686; Special Initiatives 686; Multidrug-resistant Tuberculosis and DOTS Plus 691; Infection Control and Hospital Waste Management 692; Information, Education and Communication 693

50. Treatment of Tuberculosis in Special Situations **695**
Rajendra Prasad
Introduction 695; Pharmacokinetics of Antitubercular Drugs 695; Treatment of Tuberculosis in Pregnancy and Lactation 696; Treatment of Tuberculosis in 696; Renal Insufficiency 696; Treatment of Tuberculosis in Liver Disease 698

51. Tuberculosis and Human Immunodeficiency Virus Infection **701**
SK Jindal
Introduction 701; Epidemiology 701; Pathogenesis 702; Clinical Effects of HIV on Tuberculosis 702; Diagnosis 704; Management 704

52. Nontuberculous Mycobacterial Infections **710**
PS Shankar, SK Jindal
Introduction 710

SECTION 8: RESPIRATORY INFECTIONS

SK Jindal

53. Community-acquired Pneumonia **719**
Charles Feldman, Ronald Anderson
Introduction 719; Epidemiology 719; Microbial Etiology of Community-Acquired Pneumonia 720; Risk Factors for Community-acquired 721; Pneumonia 721; Pathogenesis of Cap with Particular 722; Reference to the *Pneumococcus* 722; Diagnostic Testing 723; Prognosis 724; Treatment of Community-acquired 726; Pneumonia 726; Prevention of Infection—Vaccination 727

54. Pulmonary Fungal Infections **734**
Arunaloke Chakrabarti
Introduction 734; Epidemiology 734; Agents Responsible 735

55. Pulmonary Mycetoma **747**
Alladi Mohan, B Vijayalakshmi Devi, Abha Chandra
Introduction 747; Pathogenesis 747; Pathology 747; Clinical Presentation 748; Diagnosis 749; Treatment 753; Prognostic Factors 754; Overall Mortality 754

56. Nosocomial Pneumonia **757**
Vishwanath Gella, SK Jindal
Introduction 757; Pathogenesis 757; Diagnosis 757; Risk Stratification of Patients with VAP 759; Treatment 760; Prevention of HAP and VAP 762

57. Viral Pneumonias **765**
Arjun Srinivasan, Ritesh Agarwal
Introduction 765; Respiratory Viruses 765; Presenting Features 766; Risk Factors and Features of Severe Disease 771; Respiratory Protection for Health 772; Care Professionals 772

58. Pulmonary Manifestations of Human Immunodeficiency Virus (HIV) Infection **776**
Zarir F Udwadia
Introduction 776; *Pneumocystis Jiroveci* Pneumonia (PJP) 777; Community-acquired Pneumonias (CAPs) 778

59. Lung Abscess **780**
C Ravindran, Jyothi E
Definition 780; Epidemiology 780; Classification 780; Etiology 781; Pathogenesis 781; Pathology 782; Clinical Features 783; Complications 785; Treatment 786; Prognosis 787

60. Bronchiectasis and Cystic Fibrosis **790**
David Honeybourne
Bronchiectasis 790; Cystic Fibrosis 795

61. Rare Respiratory Infections **801**
Mohankumar Thekkinkattil, S Arulmozhi
Introduction 801; Viral Infections 801; Bacterial Infections 801; Rare Forms of Tuberculous Infections 802; Chlamydial Infections 802; Parasitic Infection 803; Zoonotic Bacterial Pneumonias 804

62. Parasitic Lung Diseases **806**
VK Vijayan
Introduction 806

63. Anaerobic Bacterial Infections of the Lungs and the Pleura **820**
Ashok Shah, Chandramani Panjabi
Introduction 820; Historical Note 820; Pathophysiology 821; Natural History and Clinical Classification 822; Anaerobes and Upper Respiratory Syndromes 823; Incidence 823; Microbiology 824; Clinical Features 824; Laboratory Diagnosis 825; Radiological Manifestations 827; Treatment 827; Prognosis 828

SECTION 9: ASTHMA

SK Jindal

64. Bronchial Asthma—Epidemiology **835**
SK Jindal
Introduction 835; Definition 835; Epidemiology 835; Economic Burden 835; Epidemiological Differences 836; Factors Influencing Prevalence of Asthma 836

65. Allergic Rhinitis, Asthma and Comorbidities **840**
Ruby Pawankar, Satoko Kimura, Sachiko Mori, Yukiko Yokoyama
Introduction 840

66. Asthma Diagnosis **847**
Liesel D'silva, Parameswaran Nair
Introduction 847; Clinical Diagnosis 847; Tests for Diagnosis and Monitoring 847; Diagnostic Challenges 855

67. Airway Inflammation and Remodeling **866**
Ruby Pawankar, Shu Hashimoto, Bassam Mahboub, Chika Ozu
Introduction 866; Chronic Inflammation in AR and Asthma 867; Remodeling in Asthma 870

68. Control and Management of Stable Asthma **876**
Sidney S Braman, David Lee
Introduction 876; The Goals of Asthma Treatment 876; Essential Components of Asthma Care 877; Treatment Protocols for Asthma 885; Asthma Control in Developing Countries 887

69. Management of Severe Asthma **893**
Liesel D'silva, Parameswaran Nair
Introduction 893; Development of Severe Asthma 893; Phenotypes in Severe Asthma 894; Managing Severe Asthma using Airway Inflammatory 902; Monitoring a Patient with Difficult Asthma 903

70. Immunotherapy and Immunomodulators for Allergic Rhinitis and Asthma **909**
Ruby Pawankar, Giovanni Passalacqua
Introduction 909; Subcutaneous Immunotherapy (SCIT) 909; The Sublingual Route 911; Future Developments of SIT 913

71. Allergen Desensitization **918**
Vikram Jaggi
Introduction 918; Definition 918; Historical Background 918; Mechanisms of Allergen Immunotherapy 919; Future Directions 923

72. Bronchodilators **926**
Samir Malhotra, Nusrat Shafiq
Introduction 926; Beta-2 Adrenergic Agonists 926; Methylxanthines (Xanthines) 930; Anticholinergic Agents 931

73. Patient Education in Asthma **934**
Bharat Bhushan Sharma, Virendra Singh
Introduction 934; Goals of Asthma Education Programs 934; Benefits of Asthma Education Programs 935; Methods and Settings 935; Asthma Education Program Components 936; Patient Education: Problems 936

74. Childhood Asthma **939**
Meenu Singh
Epidemiology 939; Definition 940; Pathophysiology 940; Diagnosis 941

75. Allergic Bronchopulmonary Aspergillosis **947**
Ritesh Agarwal
Introduction 947; Epidemiology of ABPA 948; Pathogenesis of Abpa 949; Pathology of ABPA 949

SECTION 10: CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Sundeep Salvi

76. Chronic Obstructive Pulmonary Disease: The Neglected Epidemic **971**
Sundeep Salvi
Mortality Due to Chronic Obstructive 971; Pulmonary Disease 971; Morbidity Due to COPD 971; The Economic Burden of COPD 971; Risk Factors for COPD 971, Primary and Secondary Prevention of COPD 973

77. Health and Economic Burden of Chronic Obstructive Pulmonary Disease **975**
Monica Barne, Sundeep Salvi
Introduction 975; Mortality Due to COPD 975; Prevalence of COPD 979; Disability-adjusted Life Years Due to COPD 983; Economic Burden of COPD 984

78. Risk Factors for Chronic Obstructive Pulmonary Disease **987**
Sneha Limaye, Sundeep Salvi
Introduction 987; Tobacco Smoking 987; Indoor Air Pollution as a Risk Factor for COPD 988; Outdoor Air Pollution and COPD 989; COPD Associated with Occupational Exposures 989; Copd Associated with Pulmonary Tuberculosis 989; Chronic Asthma as a Risk Factor for COPD 990; Genetic Factors 991; Socioeconomic Status 991

79. Pathophysiology of Chronic Obstructive Pulmonary Disease **993**
Bill Brashier, Sundeep Salvi
Introduction 993

80. Pulmonary Function Testing in Chronic Obstructive Pulmonary Disease **1015**
Tavpritesh Sethi, Anurag Agrawal
History and Evolution 1015; The Clinical Need for Pulmonary Function Tests 1016; Physiological Principles 1016; Clinical Applications 1019; Measuring Small Airway Disease: Impulse Oscillometry 1022; Other Tests 1023; The Future 1025

81. Systemic Manifestations and Comorbidities **1027**
SK Jindal, PS Shankar
Introduction 1027; Pathogenesis 1027; Systemic Manifestations 1028; Therapeutic Considerations 1030

82. Role of Infections in Chronic Obstructive Pulmonary Disease **1033**
Suruchi Mandrekar, Sundeep Salvi
Introduction 1033; Do Bacteria Cause/Initiate COPD? 1033

83. Treatment of Chronic Obstructive Pulmonary Disease **1041**
Peter J Barnes
Introduction 1041; Risk Factors and their Prevention 1041; Other Drug Therapies 1049; Non-pharmacological Treatments 1050; Managing Chronic Disease 1051; Treatment of Acute Exacerbations 1051; Treatment of Cor Pulmonale 1052; Future Therapies 1052

84. Acute Exacerbations of Chronic Obstructive Pulmonary Disease **1056**
Raja Dhar, AG Ghoshal
Introduction 1056; COPD Exacerbation 1056; Assisted Ventilation 1061

85. Long-term Oxygen Therapy **1065**
R Agarwal, SK Jindal
Selection of Patients 1065; Benefits 1066; Perspectives of Domiciliary Oxygen Use in India 1071

86. Patient Education in Chronic Obstructive Pulmonary Disease **1073**
Tushar Sahasrabudhe
Introduction 1073; Education about the Disease 1073; Education to Help Reduce COPD 1075; Exacerbations 1075; Education for Improving Baseline Lung 1075; Function 1075; Pulmonary Rehabilitation 1076; Education and Discussion on Daily Life 1077; Issues 1077; Discussion on Special Issues 1077; Prevention of COPD 1078; Early Detection of COPD 1078

87. End-of-life Communication and Palliative Care in Advanced COPD **1080**
Sujeet Rajan
Introduction 1080; Advanced Terminal COPD 1080; Prognosis of Advanced COPD 1080; Good Death in COPD: Implications 1081; Principles of End-of-life Communication in COPD 1082

88. Smoking/Tobacco Control **1085**
Virendra Singh, Bharat Bhushan Sharma
Introduction 1085; Tobacco Smoking 1085; Smoking Control Interventions 1089

89. Pulmonary Rehabilitation **1097**
Rachael A Evans, Roger S Goldstein
Symptoms and Disability Associated with Chronic Obstructive Pulmonary Disease 1097; The Role and Definition of Pulmonary 1098; Rehabilitation 1098; Future Work 1106

90. Upper and Central Airway Obstruction **1109**
VR Pattabhi Raman
Introduction 1109; Acute UAO 1112; Chronic UAO 1113; Therapeutic Considerations 1120

91. Bronchiolar and Bullous Lung Diseases **1123**
Gyanendra Agrawal, Dheeraj Gupta
Introduction 1123; Bronchiolitis 1123; Bullous Disease of the Lung 1132

92. Immunomodulators in Respiratory Diseases **1138**
Agam Vora
Introduction 1138

SECTION 11: INTERSTITIAL LUNG DISEASE

Dheeraj Gupta

93. Approach to Diagnosis of Interstitial Lung Disease **1145**
Dheeraj Gupta
Introduction 1145; Etiology and Classification 1145; Epidemiology 1147; Pathology 1147; Pathogenesis 1148; Diagnostic Approach 1149; Management 1151; Acute Exacerbation of ILD 1155; Prognosis 1155

94. Pathology of Interstitial Lung Disease **1160**
Amanjit Bal, Kusum Joshi
Idiopathic Interstitial Pneumonia 1160; Idiopathic Bronchiolocentric Interstitial Pneumonia (BRIP)/Airway Centered Interstitial Fibrosis 1167; Drug Induced Interstitial 1168; Lung Disease (DIILD) 1168; Connective Tissue Disorder Associated Interstitial Lung Disease 1169; Hypersensitivity Pneumonitis (HP) 1170; Lymphangioleiomyomatosis (LAM) 1170; Pulmonary Langerhans Cell Histiocytosis (LCH) 1171

95. Idiopathic Interstitial Pneumonias **1174**
H Shigemitsu, Ngozi Orjioke
Introduction 1174; Epidemiology 1174; Classification 1174; Clinical Features 1174; Histological Features 1176; Treatment 1177; Idiopathic Pulmonary Fibrosis (IPF) 1177; Nonspecific Interstitial Pneumonias (NSIP) 1180; Desquamative Interstitial Pneumonia (DIP) 1181; Respiratory Bronchiolitis-associated Interstitial Lung Disease (RB-ILD) 1182; Cryptogenic Organizing Pneumonia (COP) 1182; Acute Interstitial Pneumonia (AIP) 1184; Lymphoid Interstitial Pneumonia (LIP) 1185

96. Sarcoidosis **1188**
Dheeraj Gupta, Om P Sharma
Introduction 1188; History and Epidemiology 1188; Risk Factors 1189; Pathogenesis and Immunology 1191; Pathology 1192; Clinical Features 1192; Diagnosis 1199; The Tuberculosis Enigma 1201; Treatment 1202; Prognosis and Mortality 1207; Future Directions 1208

97. Pulmonary Eosinophilic Disorders **1217**
Subhash Varma, Aditya Jindal
Introduction 1217; Pulmonary Eosinophilic Disorders 1218; Approach to Diagnosis and Conclusion 1225

98. Infiltrative and Deposition Diseases **1229**
Pralay Sarkar, Arunabh Talwar
Introduction 1229; Pulmonary Amyloidosis 1229; Lysosomal Storage Disorders 1236

SECTION 12: DISORDERS DUE TO ENVIRONMENTAL AND CLIMATE FACTORS

SK Jindal

99. Outdoor Air Pollution and Respiratory Health **1255**
Sara Maio, Sandra Baldacci, Marzia Simoni, Fabio Cibella, Giovanni Viegi
Introduction 1255; Outdoor Air Pollution Effects 1255

100. **Indoor Air Pollution and Respiratory Health** **1266**
Marzia Simoni, Sara Maio, Sandra Baldacci, Fabio Cibella, Giovanni Viegi
Introduction 1266; Prevention and Conclusion 1272

101. **Environmental Risk Factors for Respiratory Disease** **1275**
Kalpana Balakrishnan
Introduction 1275; Environmental Risk Factors 1275

102. **Climate Change and Lung Disease—With Special Focus on Developing Countries** **1288**
Kin Bong Hubert Lam, Jon G Ayres
Climate Change: An Introduction 1288; Future Projections of Climate Change 1289; Impact of Climate Change on Health 1289; Climate Change and Lung Disease 1289; Synergy between Air Pollution and Temperature 1292

103. **High Altitude Problems** **1296**
Ajay Handa
Introduction 1296

104. **Aviation and Space Travel** **1301**
Ajay Handa
Air Travel 1301; Space Travel 1303

105. **Diving Medicine** **1307**
Angeline Lazarus, Richard Mahon
Historical Background 1307; Diving Physics and Physiology 1307; Types of Diving 1308; Diving-related Injuries/Illnesses 1309; Decompression Sickness 1310; Barotrauma 1312; Nitrogen Narcosis 1314; Pulmonary Edema 1314; Treatment of Decompression Disorders 1314; Long-term Effects of Diving 1316

SECTION 13: OCCUPATIONAL DISORDERS

PS Shankar

106. **Lung Diseases in Coal Workers** **1325**
Harakh V Dedhia, Daniel E Banks
Introduction 1325; Clinical Features of Coal Dust Exposure 1326; Pathology of CWP 1328; Management of CWP 1332

107. **Silicosis** **1335**
PS Shankar, SK Jindal
Introduction 1335

108. **Berylliosis** **1345**
PS Shankar
Introduction 1345; Pathogenesis 1345; Clinical and Radiological Features 1346; Diagnosis 1346; Treatment 1347

109. **Hard Metal Lung Diseases** **1348**
Dilip Maydeo, Nikhil Sarangdhar
Introduction 1348; Etiology and Pathogenesis 1348; Clinical Features 1349; Diagnosis 1349; Treatment 1350

110. **The Health Risks of Asbestos Exposure Inhalation** **1351**
Daniel E Banks, Harakh V Dedhia
Introduction 1351; Asbestos Fibers 1352

111. Occupational Asthma 1367
Gajanan S Gaude
Introduction 1367; Historical Aspects 1367; Definitions 1367; Epidemiology 1368; Work-exacerbated Asthma 1368; Agents Causing Occupational Asthma 1368; Pathogenetic Mechanisms of Occupational Asthma 1371; Diagnosis 1374; Management 1375; Prognosis 1377; Prevention 1377

112. Hypersensitivity Pneumonitis 1380
PS Shankar
Definition 1380; Etiology 1380; Pathogenesis 1382; Pathology 1382; Clinical Presentation 1382; Investigations 1383; Diagnosis 1384; Prognosis 1385; Prevention 1385; Management 1385

113. Toxic Inhalations and Thermal Lung Injuries 1387
VK Vijayan, N Goel, R Caroli
Introduction 1387; Determinants of Inhalational Lung Injury 1387; Clinical Presentations of Inhalational Injury 1388; Specific Inhaled Toxins 1390; Systemic Illnesses from Inhaled Toxins 1395; Smoke Inhalation Lung Injury 1396; Approach to a Victim of Inhalation Injury 1397; Management 1397

114. Drug-induced Respiratory Disease 1401
William J Martin II
Introduction 1401; Drugs Associated with Respiratory Toxicity 1401; Diagnosis and Management of Drug-induced Respiratory Disease 1405

SECTION 14: PULMONARY NEOPLASMS

D Behera

115. Epidemiology and Etiopathogenesis of Lung Cancer 1411
Navneet Singh
Introduction 1411; Epidemiology 1411; Risk Factors 1412; Molecular Biology 1415

116. Pathology of Lung Tumors 1420
Ashim Das
Introduction 1420; Minor Groups 1420; Evolution of WHO Classification 1421; Neuroendocrine Lesions of Lung 1426; Staging of Lung Tumors 1427

117. Lung Cancer: Clinical Manifestations 1429
Javaid Ahmad Malik
Introduction 1429; Local Manifestations 1429; Metastatic Manifestations 1430; Endocrine Syndromes 1436; Neurological Syndromes 1438; Hematological Syndromes 1439; Skeletal 1439; Miscellaneous Syndromes 1440

118. Diagnosis and Staging of Lung Cancer 1444
Ajmal Khan, Navneet Singh
Introduction 1444; Diagnosis of Lung Cancer 1444; Staging of Non-small Cell Lung Cancer 1446; Staging of Small Cell Lung Cancer 1453

119. Approach to Management of Lung Tumors 1457
Navneet Singh, D Behera
Introduction 1457; Diagnostic Work-up 1457; Treatment Planning 1458; Palliation 1463

120A. Solitary Pulmonary Nodule 1470
Alladi Mohan, B Vijayalakshmi Devi, Abha Chandra
Introduction 1470; Terminology 1470; Epidemiology 1471; Etiology 1471; Clinical Evaluation 1471; Imaging Studies 1472; Management 1478

120B. Hematopoietic and Lymphoid Neoplasm of Lungs **1482**
Pankaj Malhotra
Introduction 1482; Lymphomas 1482; Lymphomatoid Granulomatosis (LYG) 1488; Secondary Involvement of Lung by Other Systemic Hematopoietic and Lymphoid Disorders 1488; Pyothorax Associated Lymphomas 1489

121. Mediastinal Disorders **1492**
Arjun Srinivasan, SK Jindal
Introduction 1492; Imaging of Mediastinum 1493; Differential Diagnosis 1494; Mediastinitis 1495; Tumors and Cysts of Mediastinum 1496; Anterior Mediastinal Mass 1497; Tumors of the Middle Mediastinum 1500; Tumors of the Posterior Mediastinum 1501; Tumors of Autonomic Nervous System 1501; Superior Vena Cava Syndrome (SVCS) 1502

122. Diseases of Thoracic Cage **1504**
Balamugesh T
Introduction 1504; Kyphoscoliosis 1504; Pectus Excavatum 1506; Pectus Carinatum 1508; Ankylosing Spondylosis 1508; Obesity 1508; Flail Chest 1509; Miscellaneous Conditions 1509

123. Diseases of Diaphragm **1513**
Balamugesh T
Introduction 1513

SECTION 15: PULMONARY CIRCULATORY DISORDERS

Ritesh Agarwal

124. Diffuse Alveolar Hemorrhage Syndromes, Wegener's Granulomatosis and Other Pulmonary Vasculitis **1523**
Eleni Stagaki, Vlasis Polychronopoulos
Diffuse Alveolar Hemorrhage Syndromes 1523; Wegener's Granulomatosis and Other Pulmonary Vasculitides, 1525; ANCA 1527

125. Pulmonary Hypertension: A Third World Prospective **1535**
Zeenat Safdar
Introduction 1535; Clinical Features 1536; Diagnostic Evaluation 1536; Pathophysiology 1539; Management 1539

126. Pulmonary Thromboembolism **1546**
Devasahayam J Christopher, Richa Gupta
Introduction 1546; Epidemiology 1546; Pathophysiology 1546; Risk Factors 1547; Clinical Features 1549; Diagnosis 1550; Clinical Probability Assessment 1552; Diagnostic Strategies 1553; Assessment of Prognosis 1553; Management 1555

127. Pulmonary Vascular Malformations **1562**
Gautam Ahluwalia
Introduction 1562; Pathogenesis 1563; Clinical Features 1563; Investigations 1564; Management 1564; Other Pulmonary Vascular 1565; Malformations 1565

SECTION 16: RESPIRATORY SLEEP DISORDERS

Ashutosh N Aggarwal

128. Approach to Respiratory Sleep Disorders **1571**
Ahmad Abdelwahed, Jeremy A Weingarten
Introduction 1571; Sleep History 1571; Physical Examination for Respiratory Sleep Disorders 1572; Nocturnal Polysomnography 1573; Portable Monitoring 1574; Sleep Questionnaires 1576; Respiratory Disorders During Sleep 1576; COPD 1577

129A. Obstructive Sleep Apnea-hypopnea Syndrome—A Developing Countries' Perspective 1580
Harmanjit Singh Hira

129B. Obstructive Sleep Apnea 1593
Macy MS Lui, Mary SM Ip
Introduction 1593; Epidemiology and Risk Factors 1593; Pathogenesis of OSA 1595; Clinical Features 1596; Diagnosis 1597; Morbidities Associated With OSA 1599; Treatment 1600

SECTION 17: RESPIRATORY CRITICAL CARE

R Agarwal, SK Jindal

130. Respiratory Failure 1609
Karthik Gnanapandithan, Ritesh Agarwal
Definition 1609; Classification 1609

131. Acute Respiratory Distress Syndrome 1618
Jean I Keddissi, D Robert McCaffree

132. Sepsis 1631
Sean E Hesselbacher, Kalpalatha K Guntupalli
Introduction 1631

133. Nonpulmonary Critical Care 1647
Adebayo Esan, Lavanya Irugulapati, Liziamma George
Introduction 1647; Gastrointestinal Disease in Critical Care 1647; Hematology in Critical Care 1656; Renal Disease in Critical Care 1661; Endocrine Emergencies in Critical Care 1664; Neurological Disorders in Critical Care 1670

134. Poisoning, Envenomation and Environmental Injuries 1687
Dhruva Chaudhry, Inder Pal Singh, Deepak Govil
Introduction 1687; Poisoning 1687; Stings and Envenomation 1699; Environmental Injuries 1702

135. Obstetric Critical Care 1709
Hrishikesh S Kulkarni, Dilip R Karnad, Kalpalatha K Guntupalli
Introduction 1709; Obstetric Hemorrhage 1710; Acute Hypertensive Disorders in Obstetric Critical Care 1713; Venous Thromboembolism (VTE) in Pregnancy 1716; Cardiac Disease in Pregnancy 1716; Respiratory Disorders in Pregnancy 1719; Amniotic Fluid Embolism 1719; Liver Dysfunction in Pregnancy 1720; Renal Dysfunction in Pregnancy 1720; Infection in Pregnancy 1721

136. Cardiac Emergencies in the Intensive Care Unit: Cardiac Arrhythmias 1726
Mohamed S Rahman, M Eyman Mortada
Introduction 1726; Premature Ventricular Complexes (PVCs) 1726; Accelerated Idioventricular Rhythm 1726; Wide Complex Tachycardia 1728; Supraventricular Tachycardia 1733; Bradycardia (Heart Rate <60 bpm) 1742

137. Cardiac Emergencies in the Intensive Care Unit: Cardiogenic Shock and Acute Coronary Syndrome 1746
M Fuad Jan, Suhail Allaqaband

History of Respiratory Medicine

FE Udwadia

INTRODUCTION

The history of respiratory medicine cannot be separated from the overall history of medicine. The history of all medicine, including respiratory medicine begins with the history of man, for even primitive man realized that when a man ceases to breathe, he ceases to live. It needs also to be remembered that the history of medicine, like the history of the world is a chronicle of change. We in the present have built on triumphs and defeats of the past, just as those in the future will build on the successes and failures of the present.

> "Time present and time past
> Are both perhaps present in time future,
> And time future contained in time past."

Religion ruled medicine in the ancient past; then came empiricism and then came science. Even today, medicine, including respiratory medicine, is a mixture of science and empiricism. In ancient ayurveda "phlegm" (kapha), or secretions within the chest was one of the three "humors" that regulated the body, the other two being wind (vat) and choler (pitta). The Greeks paid the same importance to the humor "phlegm," but included a fourth humor "blood" and omitted "wind" from their concept of humors.

It was Hippocrates, the father of medicine (460–377 BC) teaching on the island of Kos, Greece, who divorced religion from medicine and who taught that disease was due to extraneous factors and influences. He introduced the importance of clinical bedside medicine, the important of history, physical examination, and the documentation of a patient's illness. His clinical description of diseases considering the meager facilities in that age remains unsurpassed to this day and still makes fascinating reading. Among the numerous descriptions of different diseases, one also finds a description of the clinical features of tuberculosis, a disease which still plagues the developing world. Tuberculosis is an ancient disease. The earliest evidence of this disease comes from a female skeleton unearthed from a cave in Liguria, Italy dating back to around 5300 BC. Besides a description of tuberculosis in Hippocratic writings, there was awareness of the clinical features of tuberculosis in the Rig Veda scriptures (around 1500 BC) and in texts of Ayurveda (second century AD). Ancient Chinese texts as early as in the third millennium BC, the famous Egyptian George Ebers Papyrus from Thebes (1550 BC) and the Edwin Smith Papyrus (1600 BC) also give descriptions of the disease.

After Hippocrates came many contributors to medicine. The most famous of these was Claudius Galen (AD 138–201). He indeed may be considered the most influential writer of all time, as his writings in medicine became fossilized as gospel truth for almost 1500 years. Though great for his era, Galen based his deductions and theories on observations following his dissection of animals, so that among some truths that he propounded, there lay buried numerous mistakes, which hindered the progress of medicine for well over a thousand years. One of his greatest mistakes was the propagation of his belief that the blood from the right ventricle reached the left ventricle through pores (invisible small openings) within the interventricular septum. His view on the circulation of blood in humans was really a figment of imagination, yet it stood for close to 1500 years after his demise. Why should this have been so? It is because dissection of the human body was considered taboo in that day and age so that many of his hypotheses lacked the fundamentals of scientific observation, and study.

After the decline and fall of the Roman empire (410 AD) the Western World was enveloped in the Dark Ages—war, disease and anarchy prevailed. The Dark Ages (470 AD to 1000 AD) slowly gave way to the Renaissance, a brilliant period in the history of Man.

Many medical historians are of the opinion that the history of modern medicine began with the publication in 1543 of "De Humanis Corporis Fabrica" by Andreas Vesalius, a 25 year old young man who was professor of anatomy in the University of Padua, Italy. Vesalius dissected the human body and through meticulous observation and description illustrated the musculoskeletal framework as also the internal structure of the body in the form of exquisitely detailed anatomical plates. These were designed and executed in the studio of the great Italian artist Titian. Vesalius exploded the numerous untruths in the teaching of Galen, which had dominated medicine for well over a thousand years. He proved above all that the ventricular septum had no pores and that blood from the right ventricle could not therefore enter the left ventricle through septal pores. Vesalius described the venous system of the thorax, discovered the azygos vein and noted its entry into the superior vena cava. His numerous contraindications of the many hypotheses put forth by Galen raised a furor of opposition from the medical fraternity who believed that the teachings of Galen were sacrosanct and could not be contradicted. Vesalius disappointed, frustrated, and almost hounded by the opposition, tore up his many manuscripts and fled Padua to become physician to Charles V and then to Philip III of Spain. He never researched on anatomy again and thus was destroyed a great man in his prime—destroyed by the bigotry, jealousy and hate of lesser mortals.

The next individual who like Vesalius contradicted Galen was Michael Servetus. How was blood to reach the left ventricle from the right ventricle if not through the pores within the septum as enunciated by Galen? Servetus had worked with Vesalius in Paris. He was Spanish, an unusual figure of the Renaissance—a humanist, a theologian and a man of medicine. In a theological treatise, Christianismi Restitutio, he briefly described the pulmonary circulation. He stated that the blood from the right ventricle had to flow thorough the pulmonary artery via its branches into the lungs. His theological treatise was judged to be heretical by the church and this brave man who thought differently from the general herd of humanity was burnt at the stale for his heresy. We however now know that Nafis, a physician from Damascus had already described the flow of blood from the right ventricle through the lungs as early as the 13th century, 400 years ahead of Servetus. The credit for the first discovery of the pulmonary circulation should therefore go to him.

The discovery of the overall circulation of blood in man, based on meticulous observation, experimentation, and for the first time on scientific principles (akin to the principles followed by Newton and Kepler who also belonged to this Baroque age—the 17th century) is one of the greatest medical discoveries of the world. Future generations could never have contributed to cardiorespiratory medicine without this monumental discovery. The credit for this discovery goes to William Harvey. He was a physician on the staff of St. Bartholomew's Hospital in London. He announced the discovery of his work in 1616. His classic work "Exercitatio anatomica de Motu Cordis et Sanguinis in Animalibus" was published rather shoddily, 12 years later in Frankfurt, in which he described circulation as we know it today. It immediately divided the world into two hostile camps—one for and one against Harvey. Truth ultimately prevailed and Harvey has the distinction of being one of the all time greats in the field of medicine.

Though Harvey published his discovery of circulation in the 17th century, knowledge in the physiology of respiration came a century and a half later. Priestley discovered oxygen, but did not realize its importance in respiration and respiratory physiology. It was Antoine Lavoisier who named Priestley's gas oxygen and noted its characteristics and its importance in respiration. He was probably France's greatest chemist, an aristocrat by birth, who unfortunately was guillotined during the turbulent times of the French revolution.

Bernardino Ramazzini (1633–1714) pioneered the science of occupational diseases. He wrote on silicosis in stone masons and in miners working in mines. Over the next 300 years, occupational lung diseases have graduated into an important subspecialty of pulmonary medicine.

1800–2000

I shall introduce this period with none other than the great French physician René-Théophile-Hyacinthe Laennec (1781–1836) who is an immortal in the history of medicine. A pupil of Nicolas Corvisart, the first cardiologist in the Western world and also the personal physician of Napoleon Bonaparte, Laennec was a physician at Salpétrière Hospital and the chief at the

Necker Hospital in Paris in 1814. Corvisart, Laennec and others would place their ears directly to the chest to hear heart sounds. Laennec for years has been obsessed to hear sounds within the chest with greater clarity. It is said that one day when crossing the Louvre (the residential palace of the Bourbon Kings of France), he saw a boy listening with his ear to one end of a beam to scratches made by another boy with a nail at the other end of the beam. He was struck by the ease with which sound was conducted in this manner. In 1816, a young stout woman consulted him for symptoms of heart disease. Her young age and obesity did not permit him to put his ear directly to her chest (direct auscultation). He lightly rolled up a thick sheaf of paper, placing one end over the precordium and the other end over his ear. To his surprise, he could hear the heart sounds with far greater clarity than ever before, when he used to place his ear directly to the chest. He grasped the significance of this discovery and noted that the method of indirect auscultation would enable one to hear not only the beating of the heart, but likewise all movement capable of producing sound in the thoracic cavity.

Laennec in his treatise on "Mediate Auscultation" described his first monaural stethoscope, a wooden piece 9" long, 1½ inches in diameter. It was made in two pieces, the detachable earpiece and the chest piece, which could be screwed together. Following minor modifications, by the 19th century, rubber tubing was introduced to create a flexible monaural stethoscope. Finally, the familiar two ear instrument with rubber tubings was devised by the American physician George P Cammann in 1852. Laennec made excellent use of his invention, studied both normal and abnormal breath sounds, described them in detail and drew conclusions from what he heard as to the nature and extent of the disease in the chest. Above all, he verified his findings with what was revealed at autopsy. He was the first man to create a diagnostic system of auscultatory findings in the diagnosis of pulmonary and cardiac disease. He described and gave the correct significance to adventitious sounds—rhonchi, râles, and through his system of mediate auscultation diagnosed pulmonary ailments such as bronchitis, pneumonia and tuberculosis.

Laennec's treatise on "Mediate Auscultation" focused particularly on pulmonary tuberculosis, which was prevalent all over the world in the 19th century. He described the early diagnosis of tuberculosis. He noted the presence of the tuberculous nodule, which was ubiquitous in every organ affected by the disease. On this basis he postulated that tuberculosis was a single disease, which could affect many organ systems. This was indeed a remarkable observation considering that the tubercle bacillus causing the disease had not been discovered in Laennec's time. Laennec unfortunately himself suffered from and succumbed to tuberculosis—as did many of his contemporaries, including the surgical student and poet John Keats. Laennec, brilliant though he was, did arrive at some erroneous conclusions. He denied that tuberculosis was contagious when it was strongly so; he believed that it was often hereditary when it was not so. He felt that psychological factors such as grief, sorrow, and unrequited love played a role in its causation and perpetuation. Laennec's superb writings prompted Thomas Addison, the English physician to remark that Laennec contributed more to the advancement of medical art than any other single individual.

There were many great individuals during and after Laennec's time. Mention must be made of the German School of Medicine and of Rudolf Ludwig Karl Virchow who dominated medicine for more than half of the 19th century. He was unquestionably one of the greatest pathologists who ever lived and was a worthy successor to the great pathologists, Morgagni and Rokitansky. He noted that the cell was the seat of disease and described the macroscopic and microscopic changes of several diseases, including those of the lung. He was the first to show that pulmonary emboli arose from venous thrombi chiefly present in veins of the lower extremities. His work was embodied in his opus – Di cellular – pathologie. It is worth noting that none of this work would have been possible had it not been for the discovery of the microscope by the Dutch draper Anton-van Leeuwenhoek, illustrating what has been stated at the beginning of this chapter, that the history of respiratory medicine is inseparable from medicine as a whole.

We now go on to briefly mention just two of the many great microbe hunters in the history of medicine. Till the early part of the 19th century, disease was thought to be caused by miasmas, humors or vapors. The miasmic theory of disease was challenged by many, but ultimately shattered by Louis Pasteur, a French chemist who was born in December 1822 and who went on to study chemistry at the École Nationale in Paris. He contended through meticulous experimentation and observation that all infectious diseases were caused by microorganisms and that a specific microorganism was responsible for a specific disease. He postulated that if these microorganisms could be identified, specific vaccines could be prepared and could well prevent specific disease. This was a principle enunciated in relation to all infectious diseases, including those involving the respiratory system. It behooves the world to remember that it was a chemist and not a man trained in medicine who became one of the greatest benefactors of mankind.

Pasteur's counterpart in Germany was Robert Koch, a great microbiologist. Koch's greatest triumphs was his discovery that tuberculosis was caused by a specific organism—*Mycobacterium tuberculosis*. In 1882, Koch cultured the tubercle bacillus presenting his results in 1884 to the Berlin Physiological Society. He also presented in his paper, Koch's postulates, enunciating a specific discipline, which needs to be fulfilled if a specific organism is to be considered responsible for a specific disease.

The history of tuberculosis now became increasingly complete. The disease could be diagnosed clinically ever since the brilliant clinical description of Laennec. The morbid anatomy had been determined by Morgagni, Rokitansky and Virchow. The possibility that tuberculosis was a communicable disease was entertained by a few prominent clinicians and pathologists. And at last came the cause of the disease, which till the discovery of the tubercle bacillus was deemed a mystery. Yet even great minds make mistakes. In 1890, Koch announced at the Berlin International Congress that he had discovered a substance that could cure tuberculosis; a substance that could inhibit the growth of the tubercle bacillus in the test tube as also in human beings. This substance (which he kept secret for a while) was none other than a glycerin extract of the tubercle bacillus termed tuberculin. Tuberculin was administered to thousands of individuals over the next year. The treatment proved a fiasco to the embarrassment of the great Robert Koch. Yet in years to come the preparation of tuberculin did have diagnostic use; an intradermal injection of tuberculin would often produce a strong reaction if the patient in the past or present had been infected by tuberculosis. Even today, the tuberculin test is a worthy diagnostic aid to infection caused by the tubercle bacillus.

We must now add a post-script to the story of tuberculosis. The search of a vaccine or other means of immunization against this disease continued and continues to this day. Albert Calmette of the Pasteur Institute and Jean Marie Guérin developed a new method of preparing a vaccine. They used the live bovine strain of the tubercle bacillus and on repeated subcultures of this strain noted that the bacillus lost its virulence, but retained its protective action. The vaccine was named BCG (Bacillus Calmette-Guérin) and from 1924 was tried out on humans. Thousands of children were vaccinated. Its efficacy was controversial. Recent work bears out its usefulness, particularly in the prevention of tuberculous meningitis, one of the worst forms of tuberculosis, which invariably caused death before the advent of anti-tuberculosis drugs.

Mention must be made at this point of one of the unfortunate disasters in respiratory medicine. The disaster occurred in Lubeck, Germany, in 1930, when 249 babies who were supposed to be injected with BCG vaccine were inadvertently injected with a living virulent strain of *Mycobacterium tuberculosis*. Seventy-six babies died of progressive tuberculosis. The remaining developed mild tuberculosis, but were alive at the end of 12 years, pointing perhaps to the remarkable immunological defenses the human body is endowed with.

One of the greatest discoveries of the late 19th century was William Roentgen's discovery of X-rays in 1895 — again a discovery of a physicist and not by a man trained in medicine. Radiographic examination of the chest with increasing refinements proved an invaluable asset not only in the diagnosis of pulmonary tuberculosis, but of numerous other pulmonary diseases—both infectious and noninfectious in etiology.

In 1898, Gustav Killian reported his experience with the first bronchoscopy. Technical developments over several years established bronchoscopy through a rigid bronchoscope as an important diagnostic and therapeutic modality in respiratory medicine. In 1967, Ikeda in Japan devised the flexible fiberoptic bronchoscope and this opened up new horizons following the widespread use of fiberoptic bronchoscopy in pulmonary medicine.

THE DISCOVERY OF CHEMOTHERAPY AND ANTIBIOTICS

The diagnosis of respiratory diseases using clinical methods, microbiology and a radiographic examination of the chest, was increasingly possible. But how was one to treat respiratory and other diseases? It was Paul Ehrlich, a disciple of Robert Koch who invented the concept of chemotherapy—the administration of a chemical substance to treat disease. In 1905, after several experiments, Paul Ehrlich discovered the first antimicrobial agent to treat syphilis. In 1925 Gerhard Dogmak invented Prontosil, the first of the sulfa drugs to be used against several microorganisms. More refined and less toxic sulfa drugs continue to be used in modern medicine. Finally, in 1929 came the great discovery of the antibiotic penicillin (a substance produced by the fungus *Penicillium notatum*), by Alexander Fleming which was available for clinical use in 1944 through the brilliant work of Chain and Florey. This discovery revolutionized the treatment of a number of incurable acute infections. Research on antibacterial effects of several fungi and moulds continued unabated. In 1942, Selman Waksman, a Russian Jew who had migrated to the USA and had become a microbiologist, discovered streptomycin from the fungus *Streptomyces griseus*. This drug was the first effective drug against the tubercle bacillus. Unfortunately, the use of this drug alone led to the multiplication of resistant strains. After that followed a quick discovery of other drugs against tuberculosis and other microorganisms. The impetus to the discovery of other drugs against tuberculosis was partly due to the fact that the tubercle bacillus quickly became resistant to the use of a single drug regime. The discovery of Para-aminosalicylic Acid (PAS) was followed in 1950 by the discovery of isoniazid. Excellent clinical trials in Edinburgh by Professor John Crofton and his team showed that the combined use of streptomycin, PAS and isoniazid almost always resulted in a cure if taken meticulously and regularly for the prescribed period of time. Poor compliance invariably resulted in resistant strains. The next few decades saw tremendous research on other drugs to counter the growing menace of tuberculosis. Numerous drugs have come into use, but other than rifampicin, none of these drugs in use can match the efficacy of streptomycin and isoniazid. The introduction of isoniazid in 1950 and rifampicin in 1965 paved the way for modern short-course chemotherapy, which was first introduced in the 1970s.

In India initial efforts to combat tuberculosis were spearheaded by voluntary organizations and by the setting up of sanatoria in temperate hill stations. After India's independence in 1947 two pioneering institutions were established—The Tuberculosis Chemotherapy Centre in Chennai and the National Tuberculosis Institute in Bengaluru under the Indian Council of Medical Research and the Government of India respectively. These two institutes did pioneering research to help shape tuberculosis control in India and to an extent in other countries. The famous Madras chemotherapeutic trial showed that domiciliary treatment of patients with tuberculosis was successful notwithstanding poor living conditions and a poor diet, provided there was compliance to therapy. This led to a closure of sanatoria all over world. Several intermittent chemotherapy regimes were also devised by the Madras and Bangalore centers in collaboration with the British Research Medical Council. This indeed was excellent research in respiratory medicine the like of which has not been equalled in subsequent years in our country.

Numerous other antibiotics to counter other infections have been discovered. However indiscriminate use of antibiotics has led to the dangerous emergence of many antibiotic-resistant bacteria. These indeed pose a great health hazard particularly in critical care units and in patients who are immunocompromised.

Respiratory Physiology

The exchange of oxygen and carbon dioxide within the lungs was known since the beginning of the 12th century. There however was debate whether oxygen was transferred from the alveoli to the capillary blood by active secretion or simple diffusion. August and Marie Krogh in a series of publications proved that the transfer of oxygen and carbon dioxide across the alveolar capillary membrane was a simple physical process of diffusion. Work on pulmonary function was carried out in several laboratories in Europe and America. Outstanding among these was the application of pulmonary function and pulmonary physiology to clinical respiratory medicine through the work of Comroe in San Francisco, America.

The knowledge on pulmonary physiology, gas exchange and pulmonary mechanics was put to clinical use in 1953 by Bjorn Ibsen who founded the first Intensive Care Unit in the world in Copenhagen to treat patients with poliomyelitis that had caused respiratory paralysis. This was an effective counter to the epidemic of poliomyelitis that raged in that year. Ibsen's approach incorporated the use of an endotracheal tube or a tracheostomy through which, to start with, teams of medical students working in relays pumped oxygen enriched air into the lungs of paralyzed patients till such time as they could breathe spontaneously. Soon ventilators were devised first in the form of the iron lung—a contraption in which the patient was inserted (with only the head sticking out). Negative pressure induced within the machine allowed the chest to expand and the lung to inflate. Release of the negative pressure allowed the lungs to passively deflate. An improvement over the cumbersome iron lung was the invention of the ventilator, a device which could provide positive pressure ventilatory support through an endotracheal tube or a tracheostomy to a patient in respiratory failure. Over the years, the ventilator has evolved into a superb sophisticated machine that renders mechanical ventilator support with ease and efficiency.

There is one other aspect of pulmonary medicine, which deserves an important mention. It is the epidemiological proof of the strong positive relation between cigarette and bidi smoking and cancer of the lung, and of cigarette or bidi smoking to Chronic Obstructive

TABLE 1.1: Advances in the last half century

1. A vast array of imaging techniques—in particular High Resolution Computed Tomography (HRCT). CT guided transthoracic biopsies for the evaluation of localized or peripheral lung pathologies. The discovery of Positron Emission Tomography (PET) is chiefly used in staging lung cancer.
2. The study of bronchoalveolar lavage (BAL) fluid obtained through a fiberoptic bronchoscope; the widespread use of transbronchial lung biopsy and biopsy of mediastinal glands through a flexible bronchoscope.
3. Advanced microbiological techniques; techniques for quicker cultures of *Mycobacterium tuberculosis* with quick drug sensitivity reports.
4. A thorough physiological evaluation of lung function.
5. Advanced biochemical, genetic and molecular studies; unraveling of the genome of the tubercle bacillius.
6. Improved pathological studies.
7. Powerful antibacterial drugs.
8. Antiviral drugs.
9. The development of vaccines to fight respiratory disease.
10. The development of intensive care.
11. Advanced anesthesiology and surgery, including surgery for lung transplant.

Pulmonary Disease (COPD). It was Doll and Hill who in an excellent epidemiological study in the early fifties established that the incidence of lung cancer was about 10 to 20 times greater in those who were heavy cigarette smokers compared to those who did not smoke. This was proven again and again by numerous other epidemiological studies. The incidence of lung cancer is shown to be reduced following the stoppage of smoking. The incidence of cancer in poor developing countries is on the rise mainly because of the increase in smoking habits in South and South-east Asian countries.

Advances in the last half century are too numerous to be dealt with. A few of these are briefly tabled in Table 1.1.

It is impossible to discuss each of these at length in a short chapter on the History of Respiratory Medicine, but a brief mention of the history of thoracic surgery is warranted. Carlo Forlanini (1847–1918) of Pavia attempted the first artificially induced pneumothorax in a patient with cavitative tuberculosis in 1888. The Carlo Forlanini Institute in Rome is a tribute to his memory. The rationale was to “relax” the cavity by partially collapsing the diseased lung. A more radical approach was the performance of thoracoplasty in 1930s, the posterior portions of the second to seventh ribs being removed enabling partial collapse of the lung on the affected side. This prompted healing of cavities in tuberculosis. The next advance in thoracic surgery was the resection of part or whole of the lung. The pioneer in this field was Evarts Graham (1883–1957) in Washington who first performed resection for lung cancer. Increasing skill and practice allowed for lobectomies, pneumonectomies and segmental resections. Thoracic surgery came in use not only in lung cancer, but also in other lung diseases, notably tuberculosis and suppurative lung disease. However neither tuberculosis nor cancer would allow an easy conquest.

The first lung transplantation (single lung transplant) was performed in 1963 by Hardy for a patient with a left lung cancer. The patient died after 18 days. Refinements in technique and postoperative care led finally to an improvement in the horrendous mortality experienced in the initial 20 years. Today double lung transplant and heart-lung transplant are successfully performed with a fairly good three and five years survival rate in a number of transplant centers in the world. Unfortunately lung transplant surgery has not taken off in India.

Just as old problems are solved, new problems arise. The ancient problem of tuberculosis is still a menace, particularly in developing countries. The problem is confounded by the pandemic of Human Immunodeficiency Syndrome (HIV) infection, which contributed strongly to multiple drug resistant tuberculosis and extensive drug resistant tuberculosis. Both tuberculosis and HIV infection literally fuel each other.

The introduction of Directly Observed Short-term Therapy (DOTS) in India has made an appreciable dent both in the detection rate and success rates of the treatment of tuberculosis. But much more needs to be done before India and other developing countries can claim success in the control of the disease.

One can conclude by stating that though respiratory medicine has come a long way, it still has a longer way to go. It will continue to follow a trail beset with trials and tribulations, defeats and victories, interspersed with periods of great discovery and scintillating glory.

Anatomy and Architecture: A Clinical Perspective

SK Jindal

The respiratory systems essentially comprises of three different structural and functional units:

1. Respiratory tract (from the nose and the mouth to the alveoli), meant for air conduction.
2. Lung parenchyma (the alveoli and the surrounding interstitium, which includes the blood capillaries, lymphatics and interstitial matrix with several different kinds of cells).
3. Respiratory regulatory system.

In addition, the pleura, the thoracic cage and the mediastinum, which are also important in the overall respiratory function, are considered as important constituents of the respiratory system.

LUNG ANATOMY AND MORPHOLOGY[1-5]

Respiratory Tract or Airways

Upper Respiratory Tract

The components of the upper respiratory tract include the nose, the mouth, the pharynx and the larynx upto the level of the vocal cords. The upper respiratory tract largely lies in the domain of the otorhinolaryngologists and the oral physicians, but the diseases of different parts of the upper respiratory tract may frequently pose problems in the differential diagnosis of respiratory diseases. Several different diseases may also involve both the upper and the lower respiratory tracts. Sometimes, the diseases of the upper respiratory tract, particularly of the sinuses and the larynx, may precede or predispose to the development of diseases of the lower respiratory tract. The upper respiratory tract also performs the function of filtering, warming and humidifying the inspired air, thereby playing an important role in the pulmonary defense mechanisms.

The nasal cavity is divided into two separate parts by a median septum. The floor of the nose constitutes the hard palate and the roof of the base of the skull—maxillary, ethmoid and sphenoid bones. There are three bony projections from the lateral wall of each cavity, called superior, middle and inferior turbinates and the space between the two turbinates is the meatus. Sphenoethmoidal recess is the space above the superior turbinate. The nasal cavity is surrounded by the paranasal sinuses, which are the air containing cavities in the maxillary, frontal, ethmoid and sphenoid bones and are respectively known as the maxillary, frontal, ethmoidal and sphenoidal sinuses. The sinuses, being in continuity with the respiratory tract, bear an important clinical relationship with respiratory tract diseases.

Posteriorly, the nasal cavity continues with the nasopharynx, i.e. the part of the pharynx behind the nose. The nasopharynx contains adenoids, the lymphatic tissue, which when hypertrophied may pose important challenge in the differential diagnosis of diseases, especially in the children. The openings of the Eustachian tubes, which connect with the middle-ear are also located in the nasopharynx. It is through this tube that the problems of nasopharynx may directly spread to the otherwise closed, middle-ear cavity.

Nasopharynx continues inferiorly into the oropharynx—the space behind the oral cavity, upto the hyoid bone and thereafter into the hypopharynx, which extends from the hyoid bone upto the upper end of the esophagus and the larynx.

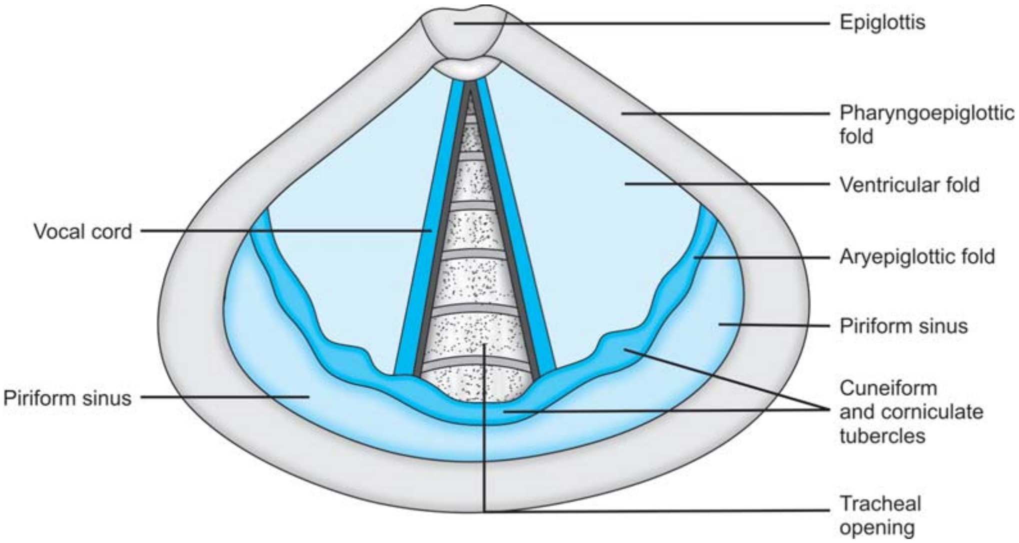

Fig. 2.1: Laryngeal opening as seen from above at the level of vocal cords

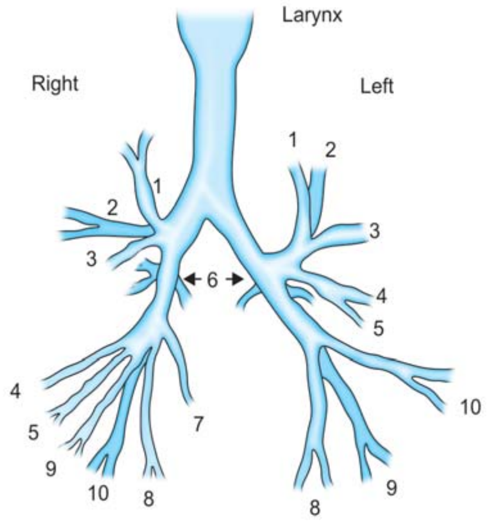
Larynx constitutes an important component of the upper respiratory tract. It is the seat of phonation and acts as sentry for the lower respiratory tract by preventing the aspiration of secretions and by regulating the flow of air. The larynx consists of several cartilages, ligaments and muscles. The laryngeal opening (Fig. 2.1) is guarded by the two vocal cords, which open with each cycle of inspiration and expiration to allow the movement of air in and out of the lungs. The vocal cords constitute both an anatomical and a functional landmark between the upper and the lower respiratory tracts. The respiratory tract below the vocal cords is normally protected from routine environmental onslaughts and is microbiologically sterile. Impaired movement or paralysis of a vocal cord compromises the respiratory defenses and is also responsible for a change in the character of the voice.

Lower Respiratory Tract

Starting with the trachea at the opening of the vocal cords, the lower respiratory tract consists of a branching system like that of a tree. The trachea divides into the two main bronchi (right and the left) which further divide into lobar, sublobar, segmental, subsegmental bronchi and the terminal bronchioles (Fig. 2.2). A single lung unit supplied by a terminal bronchiole is labeled as an acinus, which is also supplied by an independent branch of the pulmonary blood vessels and lymphatics. Acinus is an independent functional unit of the lung.



Bronchial divisions

Upper lobes : 1. Apical, 2. Posterior, 3. Anterior
Left side 4 and 5. Superior and inferior lingular
Right side (middle lobe),
4.Lateral, 5. Medial

Lower lobes : 6. Apical lower, 7. Medial (Rt. only),
8. Anterior, 9. Lateral, 10. Posterior

Fig. 2.2: Divisions of the tracheobronchial tree

The bronchial divisions up to the terminal bronchioles, primarily meant to conduct the air to the alveoli are called the "conducting airways." They do not play any role in air exchange during health. The respiratory tract beyond the terminal airways, which

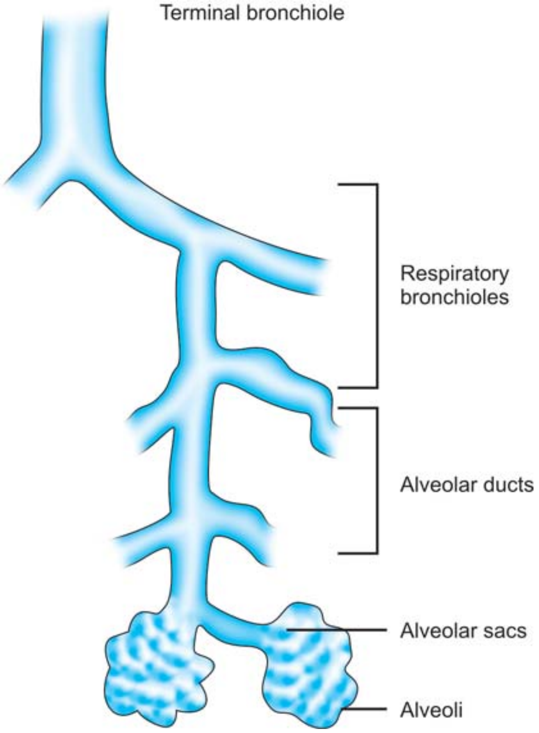


Fig. 2.3: Schematic structure of the terminal respiratory unit

plays an important role in gas-exchange, includes the respiratory bronchioles, alveolar ducts and the clusters of alveoli (Fig. 2.3). This part of the respiratory tract is therefore labeled as the "gas-exchange unit" of the lung.

The Trachea

The trachea extends from the level of the vocal cords above to the carina below. The extrathoracic part of the trachea begins at the level of the sixth cervical vertebra just below the cricoid cartilage and is covered anteriorly and laterally by the thyroid gland in the upper part of the neck. The lower part lies subcutaneously and enters the thoracic inlet, along with the esophagus situated behind the trachea. The intrathoracic part extends up to the fifth thoracic vertebra, corresponding anteriorly to the manubriosternal joint (Louis angle) and bifurcates at the carina into the right and left main bronchi.

The tracheal wall is composed of cartilaginous rings, which do not allow the tracheal tube to collapse. The cartilaginous rings are partially incomplete posteriorly and the two posterior ends are jointed together by fibrous and elastic tissue. The tracheal lumen is somewhat oval in cross-section and remains patent throughout.

Bronchial Tree and Alveoli

The right and the left main bronchi enter the right and the left lung, respectively at the lung hila. Normally, the right main bronchus, which is in direct continuity with the trachea, is broader and shorter in length while the left main bronchus is more angulated, narrower and longer. The right bronchus is therefore the preferential site for aspiration of foreign bodies and secretions, especially in the erect position.

The right main bronchus branches into the right upper lobe bronchus, which divides into apical, anterior and posterior branches and the intermediate bronchus, which further divides into middle lobe and lower lobe branches. Similarly, the left main bronchus at about 4 to 5 cm length, divides into upper and lower lobe divisions, which divides further into segmental and subsegmental branches. There are 10 segmental branches on the right and 8 segmental branches on the left side. Each generation of bronchial tree is numerically labeled with the main bronchi as the first generation bronchi (Table 2.1). There are about 8 to 10 generations of bronchial divisions, which end as terminal bronchioles, followed by three to five generations of respiratory bronchioles. The last generation of respiratory bronchioles gives rise to two to three generations of alveolar ducts, which after further branching lead to alveolar sacs, constituted by a variable number of alveoli. The alveolar ducts together with the alveolar sacs, which stem from the most proximal respiratory bronchiole constitute the terminal respiratory unit (see Fig. 2.3), which is both the structural and the functional unit of the lung. In the two adult lungs, there are about 1,50,000 units, with about 2,000 alveoli in each unit.

The alveoli actually start appearing directly from the walls of the terminal generation of respiratory bronchioles. An alveolus is generally a polyhedral air sac with a thin and flat, single cell-layered wall.

Morphological Divisions of the Lungs

The two lungs are divided into five lobes by the presence of fissures—the right lung into three and the left into two lobes. The oblique fissure on both the sides separate the upper and the lower lobes, while the horizontal fissure on the right side divides the upper lobe into the upper and the middle lobes. The oblique fissure can be drawn on the chest wall by a line from the third dorsal vertebra opposite to the spine of scapula, sloping downwards, laterally and anteriorly along the fifth rib upto the sixth costochondral junction anteriorly. The horizontal fissure on the right side may be drawn horizontally along with

TABLE 2.1: Bronchial and bronchiolar division

Structures	*Generation from*				
	Trachea	*Bronchus*	*Segmental bronchiole*	*Terminal number*	*Diameter (mm)*
Trachea	0			1	2.5
Main bronchi	1			2	11-19
Lobar bronchi	2-3			5	4.5-13.5
Segmental bronchi	3-6	0		19	4.5-6.5
Subsegmental bronchi	4-7	1		38	3 - 6
Bronchi		2-6		Variable	
Terminal bronchi		3-7		1000	1.0
Bronchioles		5-14		Variable	Variable
Terminal bronchioles		6-15	0	35000	0.65
Respiratory bronchioles			1-8	Variable	Variable
Terminal respiratory bronchioles			2-9	630,000	0.45
Alveolar ducts and sacs			4-12	14 million	0.40
Alveoli				300 million	0.25-0.3

4th costal cartilage to meet the oblique fissure in the mid axillary line. On the left side, the lingua, not separated by any fissure, is a part of the left upper lobe.

Each lobe is divided into segments by the presence of the septae. On the right side, the upper lobe is divided into apical, anterior and posterior segments; the middle lobe into the medial and the lateral segments; and the lower lobe into the lower apical (or superior) medial basal, lateral basal, anterior basal and posterior basal segments. On the left side, the upper lobe is divided into two, i.e. apicoposterior and anterior segments; the lingual into the superior and the inferior segments; and the lower lobe into the superior, anterior basal, posterior basal and the lateral basal segments. There is no medial basal segment on the left side. Therefore, the left lung contains 8 segments in comparison to 10 segments of the right lung.

Each segment is further divided into subsegments and sequentially into the lobules and the acini.

ARCHITECTURE OF LUNG PARENCHYMA[5-9]

The parenchyma of all the five lung lobes together consist of about 300 million alveoli, which when spread over, equal the surface area of a tennis court. The alveoli are surrounded by the lung interstitium comprising of loose-binding (extra-alveolar) connective tissue fibrils. The matrix of lung parenchyma consists of different materials, such as the collagen, elastin, glycosaminoglycan and fibronectin, which provide a framework of support of the alveolocapillary membrane that constitutes the bulk of the interstitium of the lung parenchyma. The major bulk is contributed by the collagen and the elastin, which together constitutes most of the interstitium—the glycosaminoglycan and fibronectin comprise only about 2% of the interstitium.

The basket-like arrangement of the matrix also allows the alveolar expansion in all directions. Within the lung interstitium, along the millions of alveoli, lie the divisions of the respiratory tract, i.e. the airways which supply air to the alveoli and the neurovascular bundles, which include the smaller branches of the pulmonary arteries, veins, the nerves and the lymphatics. The patency and the function of the airways, the alveoli and the vessels are maintained by the lung matrix. Any alternation in the structure and the function of the lung matrix affects the alveolar structure and function. Similarly, the pulmonary vasculature is also affected by the interstitial structure and disease.

An alveolar duct along with its peripheral structures is called a primary lobule. The smallest division of the lung parenchyma bounded by the connective tissue septae is the secondary lobule. A secondary lobule generally consists of two to five acini, i.e. two to five terminal bronchiole along with their peripheral structures.

These are small holes in the walls of the adjacent alveoli which are known as the pores of Kuhn. Communications may also exist between the terminal respiratory bronchioles and the alveoli through the canals of Lambert. These communications allow collateral ventilation, as well as the passage of alveolar cells and the microorganisms in a disease state.

Mucosal Lining and Lung Cells of the Respiratory Tract

Besides the gas exchange, respiratory tract mucosa performs numerous secretory, absorptive and excretory functions. There is a change of the mucosal epithelium from the nose to the alveoli. The nose, nasopharynx and the paranasal sinuses are lined by the ciliated columnar and the ciliated, stratified columnar epithelium. While the larynx is also lined by ciliated columnar epithelium, the vocal cords possess a squamous epithelium with no secretory functions. The entire lower respiratory tract up to the terminal bronchioles is lined by ciliated epithelium with the gradual transition of the columnar cells to the cuboidal and finally the squamous cells in the alveoli.

There are at least two epithelial cell types in the airway surface, of which nearly half are ciliated in nature. The cilia move the superficial liquid lining layer with their continuous beating. The glands in the submucosa of the airways are responsible for the production of airway secretions, which play an important role in the airway defense as well as the neurotransmission and endocrinal function.

The cell population of the gas exchange lung parenchyma consists of four subpopulations:

A. Epithelial
B. Endothelial
C. Interstitial
D. Alveolar macrophages.

The epithelium is essentially composed of a mosaic of lining cells, the squamous pneumocytes (Type I) and the secretory granular pneumocytes (Type II). The Type II cells are more numerous, but cover only 3% of the alveolar surface. They perform the important synthesizing and secretory functions and produce a large number of proteins including the surfactant-associated proteins and help in resorption and transepithelial exchange of fluids.

On the other hand, the Type I cells are fewer, but larger in size and cover most of the alveolar surfaces. Type I cells also express a few proteins and play some role in fluid flux. The Type I cells are complex branched cells.

There are other interspersed cells such as the brush cells (Type III), mesenchymal and the endothelial cells. The brush cells have brush borders like that of the intestinal cells with possibly an absorptive function.

The alveolar macrophages are the free cells lying within the surface layers, submerged beneath the surfactant. The alveolar macrophages are capable of self renewal by mitosis. There are also Clara cells at the level of terminal bronchioles, which produce a surfactant like material. They also secrete the aqueous (or sol) layer lining of the bronchial mucosa.

Kulchitsky or Amine Precursor Uptake and Decarboxylation (APUD) cells are the other important cells in the surface epithelium. They possess an endocrine function of producing serotonin. They also constitute the origin of the carcinoid tumors of lungs.

BLOOD SUPPLY OF LUNGS[6-12]

The lungs receive a dual blood supply from the pulmonary and the bronchial (i.e. the systemic) circulation.

Bronchial Circulation

The bronchial circulation from the left ventricle is supplied via the bronchial arteries, which arise from the aorta or its intercostals branches. Normally, there are two main divisions (right and the left) of the bronchial artery, which follow the further bronchial divisions, but both the number and the origin of the bronchial arteries are variable and inconsistent. Terminally, the bronchial arteries are divided into bronchial arterioles and capillaries to finally anastomose with the pulmonary capillaries and constitute an extensive bronchial pulmonary vascular anastomotic bed around the terminal bronchioles and the alveoli.

In healthy individuals, the bronchial circulation is small and constitutes less than 3% of the total blood supply of the lungs. It differs from the pulmonary circulation since it contains oxygenated blood from the left ventricle at systemic blood pressure levels (Table 2.2). It is primarily nutritive in its function for the tracheobronchial tree. The bronchial blood supply may enormously expand in congenital pulmonary vascular

TABLE 2.2: Differences between pulmonary and bronchial circulation of the lungs

	Pulmonary	*Bronchial*
1. Blood supply	Right ventricle	Left ventricle
2. Fraction of lung circulation	Most (> 97%)	Less than 3%
3. Arterial pressure	Pulmonary	Systemic
4. Resistance	Low	High
5. Main vessels	Large sized, elastic	Small sized, muscular
6. Function	Gas exchange	Nutritive for the bronchial tree

or right ventricular anomalies. Extensive increases may also occur following pulmonary thromboembolism, in bronchiectasis and other fibrocavitary diseases of the lungs.

Pulmonary Circulation

Pulmonary circulation constitutes the primary or the bulk of the blood supply of the lungs. The pulmonary artery arises from the right ventricle and divides into right and left main branches, which enter the hila of the lungs along with the right and left main bronchus, respectively and follow the airway divisions. They are further divided into medium-sized muscular arteries, arterioles and finally capillaries. The pulmonary venous system similarly consists of pulmonary vessels and veins, which follow a centripetal course and terminate into superior and inferior pulmonary veins, which drain into the left atrium, either independently or after joining together and forming a common trunk.

The pulmonary vessels lying in the alveolar walls are called alveolar vessels, while those lying in the loose binding connective tissue are called the extra-alveolar vessels. The alveolar vessels are directly affected by the changes in the alveolar pressure.

The pulmonary circulation is primarily concerned with the gas-exchange function of the lung. The extensive pulmonary capillary network around the alveoli provides a direct interface between the air in the alveoli and the blood in the capillaries, separated by a thin layer of alveolar epithelium, vascular endothelium and the lung interstitium. The pulmonary endothelial cells produce a large number of hormones and chemical mediators responsible for metabolic and endocrinal functions. The pulmonary circulation through an extensive capillary network around the alveoli has been conceptually equated to the presence of a sheet of blood all around the alveolus contained in a thin layer of capillary endothelium (Fig. 2.4). The capillary network crosses several alveoli before coalescing into venules, thus providing a sufficient transit time for the blood to pass from the arterial to the venous end. This allows a free exchange of gases (oxygen and carbon dioxide) through the alveolocapillary membrane. A minor fraction of pulmonary blood flow (1% to 3% of total) may pass directly from the arterial to the venous side, bypassing the alveolocapillary network. This amount of nonoxygenated blood represents the shunt fraction which is present in a normal human lung.

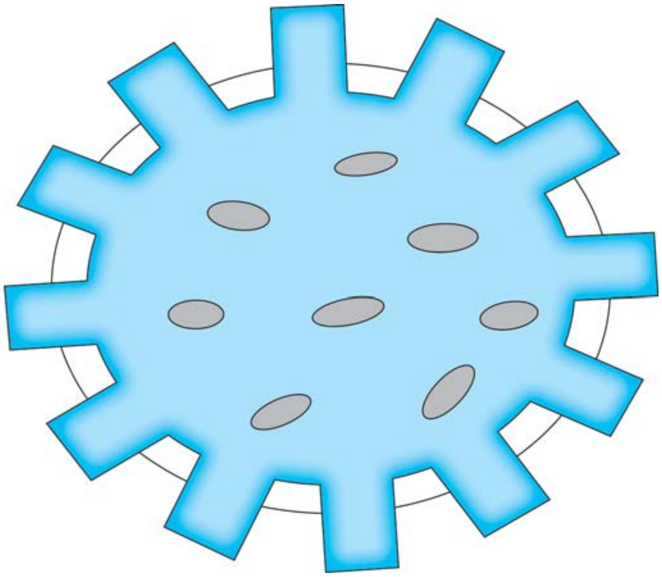

Fig. 2.4: Conceptual surface view of an alveolar wall. The capillary network when engorged, covers the whole alveolus like a sheet of blood

LYMPHATIC DRAINAGE

There are considerable variations in the lymphatic drainage of the two lungs. The lymphatics of the lungs form extensive intercommunicating networks around the bronchial and the vascular divisions in the peribronchial and the perivascular spaces. These lymphatics drain into the several groups called "stations of lymph nodes," located along the bronchial tree and ultimately into the hila (right and the left along the main bronchi) and the tracheobronchial lymph nodes. The various tracheobronchial lymph nodes groups include the superior group (between the trachea and the right or the left main bronchus) para-aortic and an inferior or infracarinal (below the carina) group. The further drainage occurs into the paratracheal glands (along both sides of trachea) and the supraclavicular glands in the neck. The paratracheal lymphatics also communicate with the paraesophageal glands in the mediastinum and the retroperitoneal abdominal nodes.

The lymphatics from all the groups of tracheobronchial nodes lead into the thoracic duct on the left side and the lymphatic duct on the right side, which finally drain into the venous system, i.e. the innominate veins of the two sides. The right lung drains into the right tracheobronchial, paratracheal and supraclavicular glands and the left lung drains into the left side glands, but there is a great degree of intercommunication between the two sides, especially of the paratracheal glands. An important exception to the same side drainage is seen for the left lower lobe lymphatics, which drain into the right-sided glands. There are also communications between the superficial and the deep lymphatic plexuses via the interlobular septal lymphatics. Thus, there is a potential for bidirectional flow of lymph.

The lymphatic drainage serves several important functions such as the removal of dust particles, toxins and microorganisms from the lungs. They also play an important role in the maintenance of lung-fluid balance. The lymph node enlargement, which occurs in several inflammatory, infective and neoplastic diseases of the lungs may therefore provide an important clue to the differential diagnosis of these diseases. Particularly in the cases of lung cancer, the site of lymph node is important in deciding the disease-stage and treatment modality.

NERVE SUPPLY[13]

The lungs are innervated by both the sympathetic and the parasympathetic autonomic nerve supply from the upper six thoracic sympathetic ganglia and the vagus, respectively. The innervation consists of afferent (i.e. the sensory) and the efferent (i.e. the motor pathways).

Parasympathetic (Cholinergic) Nerve Supply

The efferent fibers arise from the stretch receptors in the alveolar walls and lung interstitium and from epithelial irritant receptors of the airways. The afferents also arise from the irritant receptors of the laryngotracheal mucosa. They form a plexus around the carina and join the vagus nerve. The vagus nerves also contain the efferent fibers for the bronchial smooth muscles and the mucous glands. The efferent activation from irritant and stretch receptor stimulation causes the reflex efferent reaction causing bronchoconstriction and mucous hypersecretion.

Sympathetic (Adrenergic) Nerve Supply

The sympathetic efferent fibers from the upper thoracic sympathetic ganglia supply the pulmonary plexus around the carina and the sympathetic nerve, which innervate the bronchial smooth muscles, glands and the blood vessels. Sympathetic, efferent stimulation results in bronchodilatation, vasoconstriction and diminished bronchial mucous secretion. Of the various sympathetic receptor subtypes, only the β_2 and the α adrenergic receptors are present in the lungs.

The lungs are also supplied by fibers, which are neither adrenergic nor cholinergic in action. These fibers, which are carried by the vagal nerves, may play an important role in maintaining the bronchomotor tone and in the pathogenesis of bronchospastic disorders, as in asthma.

Lung Receptors

Receptors are the nerve endings, which are sensitive to specific, sensory stimuli. As stated above, the lungs are extensively supplied by stretch and irritant receptors in the alveolar and the bronchial walls, respectively. They are present in the airway epithelium, submucous region, interalveolar septa and smooth muscles. They are also present to some extent on the pleural surface. There are no pain or thermal nerve endings. The lung interstitium also contains a large number of juxtacapillary (J) receptors around the capillary walls. These receptors, also known as Paintal's J receptors, are stimulated by the parenchymal connective tissue distortion in the presence of vascular congestion and interstitial edema. The peptidergic nerve endings present around tracheal glands have species-specific excitatory or inhibitory effect on secretary function. There is also a diffuse, neuroendocrinal system (amine uptake and decarboxylation-APUD) distributed along the airway epithelium. The exact role of the APUD system is not known; it might affect the smooth muscle function.

The Pleura

The membranous covering of the lung and the pleura is an important constituent of the respiratory system, both structurally and functionally. The pleura consist of a visceral layer, which lines the outer lung surface and a parietal layer, which lines the inner surface of the thoracic cage. The two pleurae together form a continuous layer joined at the hilum to constitute a potential space, the pleural cavity, which is closed on all sides and contains a small quantity of fluid to prevent friction between the two pleural layers. There occurs an excessive fluid collection in this cavity in several inflammatory, neoplastic and other diseases involving the pleura.

The visceral lining of the pleurae also extends into the oblique and the transverse fissures to form the potential pleural space between the lung lobes in the fissures. The parts of the pleurae lining the mediastinal and the diaphragmatic surfaces, also respectively known as the mediastinal and the diaphragmatic pleura, constitute the mediastinal and the diaphragmatic pleural spaces respectively. Loculated collection of fluid may occasionally occur inside these pleural spaces in various pathological conditions.

Histologically, the pleura consists of the squamous epithelial cell lining over a connective tissue layer. The blood supply, lymphatics and nerve supply of the visceral pleura is similar to that of the lung, which it overlies. The parietal pleura is a part of the thoracic cage and derives its blood supply from the systemic circulation through the intercostals and the branches of the internal mammary arteries. Lymphatic drainage of the parietal pleura occurs to the nodes along with internal mammary artery and to the posterior mediastinal glands near the heads of the ribs. Similarly, the nerve supply of the parietal pleura is through the spinal nerves for the costal and the mediastinal pleurae and through the phrenic nerve for the diaphragmatic pleura. On the other hand, the visceral pleura is innervated by the autonomic nerves.

Thoracic Cage

The thoracic cage, which constitutes the walls of the thoracic cavity provides a protective house for the lungs, the heart, the great vessels, the esophagus and the other mediastinal structures. It is constituted by the sternum anteriorly, the thoracic spine posteriorly and the ribs and the intercostal muscles laterally. Inferiorly, the two diaphragms on each site separate the thoracic cavity from the abdominal cavity. The contents of the neck, such as the trachea, the esophagus, the neck-vessels and the nerves enter the thorax through the thoracic inlet at the upper end of the thoracic cavity. The thoracic inlet is constituted by the upper border of the manubrium sterni, the first rib and the first dorsal vertebra.

The thoracic cage not only contains the lungs and other thoracic structures, but also plays an important role in the process of respiration. The contraction of the inspiratory intercostals muscles, causing upward and forward movement of the ribs and the downward movement of diaphragms, results in the expansion of the thoracic cage and a fall in the intrapleural pressure, which causes the air to move into the tracheobronchial tree allowing the inspiration to occur. Expiration occurs after inspiratory muscle contraction ends and the thoracic cage returns to its original position. Expiration occurs as a passive phenomenon except in condition of respiratory distress when the expiratory muscles help the expiratory process through their active contraction.

The two lungs also provide a soft bed, the cardiac fossa for the heart. The inspiratory inflation and expiratory deflation of the lungs have an important bearing on the cardiac function.[14] The overall mechanical cardiopulmonary interaction provides a conducive environment for an efficient circulatory function.

Respiratory Muscles

There are three groups of muscles involved in respiration:

- The diaphragm,
- The intercostals, and
- The accessory muscles of respiration.

Diaphragm: It consists of a fan-like musculotendinous structure, which consists of muscle fibers attached to the inside of the thoracic cage at the thoracic outlet, inserted into a central tendon. Based on their attachment, the muscle fibers are grouped into three parts—the sternal part attached to the xiphoid process; the costal part attached to the inner surface of the costal cartilages and anterior ends of ribs; and the lumbar part, which is attached to the medial and the lateral lumbocostal arches. Similarly, the central tendon has got the right middle and left leaflets. The diaphragm is innervated by the phrenic nerve, which arises from the cervical plexus, with fibers from third, fourth and fifth cervical segments of the spinal cord. Phrenic nerve stimulation causes the contraction of the diaphragm, which as a result of contraction, moves down and causes lung inflation due to an increase in the volume of thorax. Weakness or paralysis of the phrenic nerves will therefore result in the elevation of the diaphragm, which will also not move with the inspiratory effort.

The thoracic mediastinal structures, such as the aorta, the esophagus, the inferior vena cava, other small vessels and nerves pass across the diaphragm to enter the abdominal cavity. There are other small recesses in the diaphragm such as the foramen of Morgagni anteriorly and the Bochdalek foramen posteriorly. Sometimes, the abdominal contents may protrude through the spaces into the thoracic cavity, i.e. the diaphragmatic or hiatus hernias. The point of esophageal entry into the abdomen serves the role of a sphincter, which allows the food to pass down into the stomach, but prevents the regurgitation of the contents into the thoracic part of esophagus. Gastroesophageal reflux, which occurs as a result of the loosening of this sphincter, plays an important role in the clinical symptomatology and etiologies of several respiratory problems.

Intercostal respiratory muscles: The intercostal muscles spread obliquely between the intercostals spaces of the ribs. The intercostals muscles directly inserted to the ribs, have no tendons. There are two groups of the intercostals muscles—the internal and the external intercostals. The external intercostal muscles arise from the lower border of the upper rib and get inserted into the upper border of the lower rib of an intercostals space. They are also called the inspiratory muscles since they actively take part in the inspiratory effort by their contraction, which by raising the ribs results in the expansion of the thoracic cavity and therefore creating a rise in the negative pressure in the pleural cavity. The internal intercostals, also called the expiratory muscles are passive during normal expiration, but assume an important role during the labored breathing in conditions causing respiratory distress when the expiration becomes an active process. The same may happen during hyperventilation, deep coughing and other similar conditions requiring a strong and active expiratory effort.

Intercostal muscles are supplied by systemic circulation through the intercostals vessels (an artery and a vein) which arise from the aorta. They are innervated by the intercostal nerves, which are derived from the inferior part of brachial plexus. The intercostal nerves along with the intercostals vessels run along the inferior borders of the ribs to supply the intercostal muscles of the respective space.

Accessory muscles of respiration: The scaleni, sternocleidomastoids, muscles of the alae nasi and of anterior abdominal wall (rectus abdominis, the external oblique, the internal oblique and the transverses abdominus) constitute the group of the accessory muscles of respiration since they assist respiration whenever an increased demand for augmented ventilation arises. Their role is rather limited in their overall contribution to the respiratory process. However, the presence of hyperactivity of accessory muscles is an important clinical indication of the underlying respiratory distress and/or failure.

Lung Development

Meenu Singh, Nidhi Anil, Amit Agarwal

INTRODUCTION

Unlike the heart, kidneys, liver and other viscera that begin their function early in the fetal life, the lungs are nonfunctional because of the aquatic environment *in utero*. The lungs start function with the first breath at birth. The process of lung development involves complex morphogenesis by means of which epithelial tubules and blood vessels are formed that ultimately give rise to airways and alveoli. Lung development primarily involves two phases, i.e. prenatal and postnatal (Table 3.1). The human lung arises from the laryngotracheal groove, which occurs approximately four to six weeks gestation.[1-3] During this time, the respiratory diverticulum (lung bud) appears ventrally to the caudal portion of the foregut. Location of the lung bud, along the gut tube is directed by various signals from the surrounding mesenchyme, including growth factors.[4,5] The proximal portion of this bud gives rise to larynx and trachea, separated by esophagus. The distal part of primitive bud gives rise to left and right main stem bronchi.

TABLE 3.1: Different phases of lung development

A. Prenatal development: Phases
  1. Embryonic stage: Day 26 to the next 7 weeks
  2. Lung development

i. Pseudoglandular	5 to 17 week
ii. Canalicular	16 to 26 week
iii. Terminal saccular	24 week to until term
iv. Alveolar	36 week to until birth and postnatally

B. Postnatal
  Alveolar stage continues up to about 18 months of age

The lung development in humans follows four distinct phases, i.e. pseudoglandular stage, which lasts from 6 to 16 weeks, during this period all major lung elements except alveoli, appear. This is followed by the canalicular stage (16 to 26 weeks) during which lumens of bronchi enlarge and become highly vascularized, by the 24 week respiratory bronchioles and alveolar buds develop. During the next phase, also known as the terminal saccular period, the blood air barrier gets established with the appearance of specialized cells of the respiratory epithelium, including the type I alveolar cells (responsible for gas exchange), and type II alveolar cells, which secrete pulmonary surfactant.[6,7] Alveolarization in humans begins after week 20 and continues up to 7 years of age, giving rise to an alveolar gas diffusion surface of 70 m^2 area and 1 μm thickness.

Development of Airway Epithelium

The development of airway epithelium occurs during the embryonic stage as previously described, it relies on the epithelial-mesenchymal interactions between the components of the airway wall including surface lining fluid, submucosal gland and the basement membrane, including the basal lamina and fibroblasts.[8-10] There occurs differential growth of the epithelial tube into a mesenchymal derivative containing the cells and the matrix. This development moves from a proximal to distal pattern following the epithelial tube. Subsequent branching of the airway tree results in producing alveolar septum.[11,12]

After the bronchial tree is established, growth occurs in two directions either longitudinally to extend the length or circumferentially to increase its diameter. In mammals, the majority of growth occurs postnatally, thereby making the perturbations by environmental contaminats crucial.[13-16] The distal airways, located at the junction between the gas exchange area and tracheobronchial tree form the extensive transition zone of the human lung. The development of submucosal glands occurs in four phases (a) formation of buds by projections of undifferentiated cells, (b) outgrowth and branching of the buds into cylinders, (c) differentiation of mucous cells in proximal tubules, (d) differentiation of serous cells in peripheral tubules and acini along with continuous proliferation of most distal areas.

Alveolar formation starts late, it is primarily a postnatal event. Besides the growth of the septae into the terminal saccules, there is formation of smooth muscles, elastin and other matrix cells.

Pulmonary Vasculature

Primitive right and left pulmonary arteries grow caudally from the aortic sac when the lung bud is also forming. They become associated with the developing respiratory primordium. The growing pulmonary arterial system maintains this association with the development of the airway system throughout thereafter. The blood supply to the respiratory primordium drains into a venous plexus that empties into the heart through a single pulmonary vein. The venous drainage system is complete around midway through gestation and corresponds to the conducting airways and arterial system.

There is only a small proportion of blood of the total cardiac output, which flows to the lungs during fetal development. The resistance to flow in the pulmonary arteries is high. After birth, there is a sudden drop in pulmonary arterial pressure and a rise in the blood flow. This is attributed partly to the anatomical alterations and partly to local vasomotor responses.

The blood circulation during fetal life takes a somewhat different route (Fig. 3.1). The oxygenated blood from the placenta is returned to the fetus through the umbilical vein and flows through the ductus venosus and inferior vena cava into the right atrium, shunted through the foramen ovale into the left atrium from where it goes to the left ventricle, aorta and gets distributed preferentially to the upper part of the body, the heart and the brain, through the brachiocephalic vessels. On the other hand, the venous blood returning to the right atrium from the superior vena cava, which is poorly oxygenated passes into the pulmonary artery through the right ventricles, gets shunted into the descending aorta (through the ductus arteriosus) from where it is distributed to the lower part of the body, the placenta. The pulmonary artery blood also flows to the lungs.

The intrauterine lung performs only the nonrespiratory functions. It does not participate in gas exchange. Importantly, it is one of the important sources of amniotic fluid and surfactant formation. It also serves as a blood reservoir, provides host defenses and participates in the activation and inactivation of biological substances.

Beginning of Postnatal Life

The lungs take over the gas exchange function immediately after delivery, which marks the end of the fetal life. With the very first breath—the cry, the ventilatory system is “turned on.” Immediately, the liquid in the lungs gets replaced with air. There occur significant changes in the pulmonary and cardiac circulation, the “normal circulation” is miraculously established with the first breath. Lung expansion gets complete during the first few breaths along with circulatory adjustments.

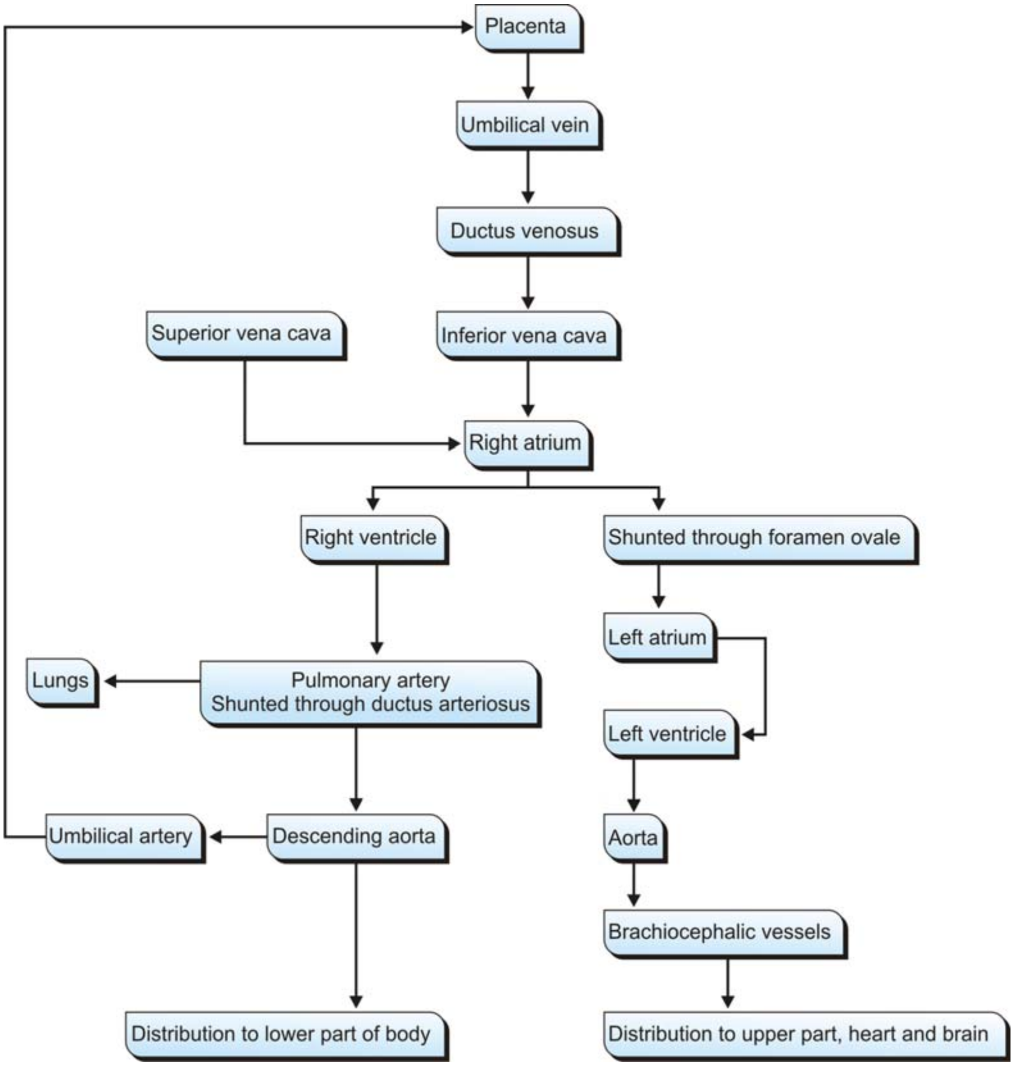
Regulatory Factors

A number of regulatory molecules are required for lung development. Lungs are formed from anterior endodermal cells that also generate the ventral foregut. Therefore, the genes (e.g. GATA-6, HNF-3B and Thyroid Transcription Factor-1) involved in ventral foregut development are important for the early lung development. Vitamin A (retinoic acid) is also essential for growth. There exists a molecular cascade that regulates and determines the growth. The knowledge of this cascade is an important area of interest to determine not only the development anomalies, but also the development of diseases, later in life.

Role of Growth Factors in Lung Development

Growth factors are known to play an important role in the development of lungs, including Platelet-Derived Growth Factor (PDGF-A and B) and their receptors PDGFR α and β are involved in the early mid stage of lung development. PGDGE-A and B mRNA level increase[17,18] in parallel with all proliferation rates during the pseudoglandular stage of lung development; cell proliferation within lung explants is inhibited by PDGF A and B antisense oligonucleotides, as well as PDGF neutralizing antibodies.[19,20]

- PDGF-A exhibits a complete failure of alveolar septation,[18] whereas the over expressions of PDGFA cause marked mesenchymal cell proliferation with in the lungs.



Placenta
Umbilical vein

Descending aorta
Aorta
Brachiocephalic vessels
Distribution to lower part of body
Distribution to upper part, heart and brain

Fig. 3.1: Schema of human fetal circulation

- PDGF-A and B have Shear Stress Responsive Elements (SSRE) in their promoter regions suggesting their expressions levels can be influenced by the exposures of cells to physical forces. This stretch-induced cell proliferation is abolished by PDFG-B and PDGF-β antisense oligonucleotides, PDGF-BB neutralizing antibodies and a PDGFR inhibitor.[21]

Vascular Endothelial Growth Factor (VEGF) exerts potent mitogenic effects on endothelial cells via the VEGF receptors (VEGFR2).[22] VEGF and VEGFR2 mRNA increase as the lung matures.[23,24] VEGF proteins plays a role in directing vascular growth in regions destined for gas exchange.

- VEGF was responsible for the endothelial cell proliferation induced by increase in lung expansion.

Insulin-Like Growth Factors (IGFs) I and II act via the type I IGF receptor.[25]

- IGF I and II mRNA levels are increased and decreased following increase and decrease in lung expansions.[26-28]
- IGF may mediate changes in lung growth induced by alterting lung expansion.

TGF-β-Transforming Growth Factor (TGF-β) inhibits fetal newborn and adult type II cell proliferation, surfactant synthesis and surfactant protein gene expression.[29-31]

- TGF-β, EGF (Epidermal growth factor) and gene deletion of this receptor prevents the attenuation of mesenchymal tissue between adjacent airways and reduces surfactant protein levels.

Fibroblast Growth Factor Family (FGF) consists of over 20 growth factors.[32]

FGF 1 and FGF 2 differ at different stages of lung development and FGF 7 (keratino growth factor KFG) proposed that KGF both enhances[33-35] and inhibits growth of the developing lung.

Parathyroid Hormone-Related Protein (PTHrP) induces surfactant protein and surfactant phospholipids biosynthesis, increases PTHrP expressions and receptor binding and enhances its effects on surfactant phospholipid synthesis.[36]

Role of Environmental Factors during Lung Development

The various regulatory mechanisms are influenced by several environmental factors and results. They significantly influence the occurrence of diseases. Hypersensitivity diseases in particular, may have their roots in *in utero* sensitization to allergens. Similarly, exposure of the fetus to tobacco smoke from a smoking mother (passive smoking) or even from other smokers in company of the pregnant mother (tertiary smoking) have been implicated in the development of allergic disorders and lung function impairment after birth.

a. *Influence of in utero exposure to allergens on development:* Exposure of the fetus to allergens inhaled by the mother during pregnancy can result in its sensitization to those allergens. In one study, neonatal peripheral blood T-cells were obtained from whole blood and stimulated with several antigens or common inhaled allergens. It is well known that maternally derived T-cell would respond to commonly encountered antigens and fetal cells would respond only to the inhaled allergens.

Maternal avoidance of allergen could influence the development of allergic reactivity in the fetus. Levels of IL-4, IL-5, IL-10 and γ-interferon were determined and compared with allergen data. They observed that the cytokine levels did not correlate with allergens.

It has been hypothesized that Th-cell cytokine patterns are determined during infancy. Although the stimulation of neonatal T-cells occurs with allergen-produced cytokine profiles. It is suggested that exposure to allergens during development may be a critical factor for the development of allergenic phenotype infants and children who are genetically predisposed to allergy.

Maternal exposure to allergens can result in a protective IgG response that may decrease the fetal sensitization. The degree of the production of gamma interferon by stimulated T-cells have a stronger likelihood of predicting the future development of atopic disease. Th-2 phenotype during pregnancy is known to favor the prenatal development of allergy, thus the interaction between environment and genetic background during *in utero* life of a human infant determines the future allergic status of the child and adult.

b. *Neonatal exposure to allergens:* Several infectious diseases are thought to have a role in either facilitating the development of allergic sensitization to inhaled allergens during the neonatal period or subverting the allergic response. The "hygiene hypothesis" (discussed later in this chapter) focuses on early exposure to bacterial products that appear to have an allergy-sparing effect. In contrast, certain viral respiratory infections have been implicated in the promotion of allergen sensitization and development of asthma. Viral infections are frequently associated with wheezing in small children. The fact that many of these children progress to become asthmatic has led to the supposition that the early viral infection may either facilitate sensitization or damage airways hyperactivity.[37] One of the major respiratory viruses that appears to have a link to asthma is Respiratory Syncytial Virus (RSV). In the severe form, RSV causes wheezing and severe bronchiolitis and often interstitial pneumonia. It was recognized in the 1980s that children with most severe RSV, accompanied by wheezing, were often subsequently diagnosed with childhood asthma. Indeed, IgE specific for viral proteins, as well as elevated histamine concentrations in respiratory fluids, were found in severely affected children.[38]

More recently, it has been found that RSV preferentially induces a Th2 cytokine environment in atopic children and in some animal models. Studies have shown that infection of Balb/c mice with human RSV induces a T-helper cell type 2 response.[39] A previous study demonstrated that some calves infected with bovine respiratory syncytial virus[40] (a closely related bovine pathogen) develop a Th2 cytokine response when infected with the virus. Indeed, infection of IgE is also associated with this model. Further work with the bovine model has demonstrated that the disease is exacerbated when allergen is inhaled during the virus infection[41] and that sensitization can be enhanced by exposure to allergen during the viral infection.[42]

In contrast to these observations, a recent study has demonstrated that in the severe cases of respiratory disease with wheezing, γ-interferon is present in elevated amount. However, in this study, the identity of the virus causing the infection and wheezing was not elucidated.[43] Following up on these observations, Garofalo et al.[44] examined the role of Th1 and Th2 cytokines, as well as several chemokines in RSV disease. They found that macrophage inflammatory protein-1α was associated with severe RSV bronchiolitis. Thus, the role of cytokines in induction of clinical disease may be different to that previously thought to stimulate the subsequent development of asthma.

SUMMARY

The respiratory system in the fetus is elegantly designed to develop from an undifferentiated epithelial tube to a complex air conducting branching system and an enormous gas-exchanging surface with a large number of differentiated cells engaged in several different functions. The immediate functional transformation and adaptation of the respiratory and circulatory systems, to the “foreign” strenuous environments after the birth is both dramatic and miraculous. Although the alveolar formation and lung development continues postnatally for some period, most of the somatic growth is complete at birth.

Genomics of Lung Diseases

L Keith Scott

INTRODUCTION

Since the discovery of Mendel's work, there have been exhaustive attempts to apply inheritance patterns to most of the diseases. However, if a disease did not satisfy traditional mendelian patterns, genetic contributions were usually discounted. This led many to look at other contributors of a disease state such as environmental factors and infectious disease-related factors. This narrow and focused research has produced much of our present understanding of diseases and generated numerous therapies. However, in spite of many successes, there were always gaps in our understanding of many diseases. Traditional views did not always explain why certain diseases progressed the way they did or why there could be person to person variation of the same disease. Many felt that the variable that influenced disease individuality was exposure, timing, pathogen virulence, coexisting disease, etc. Although these certainly do influence how a disease presents itself and progresses, these traditional contributors do not always fill our gaps in understanding.

In 2001, a preliminary map of the human genome was published.[1] This provided investigators with a new look at diseases and a new way to perceive diseases. With advances in genomic technologies allowing high throughput analysis of a large number of genes at one time, investigators began to relook at genomics in a new light and away from the traditional genetic inheritance paradigm. New tools were introduced with heavy dependence on computation and the age of bioinformatics and computational biology were born. A few years later, the map of the human genome was deemed complete, augmenting bioinformatic investigations further. This revolution began the realization that genomics is a dynamic and complex process and the simplicity of mendelian patterns but a small piece of the genomics puzzle.

GENOMICS AND DISEASE

Some diseases, such as the heart disease can be easily associated with a genetic role, even though they might not adhere to strict mendelian rules. Other disease states were not as clear and the role of genetics was less obvious. Questions has risen and problems developed that did not make sense without some contribution of an individual's genome. For example, why would one person with an apparently normal immune system acquire pneumococcal pneumonia and barely get ill, while an equally matched person developed lethal septic shock? Was it a different bug? Was that person unlucky? Only after the push to better understand the genomics of the human in health and disease, not as a function of heredity, but as a dynamic process of cellular function, some of these questions were answered. The sequencing of the human genome, along with many new technologies, have been the basis of our discovery of how dynamic the genomic transcription-translation process really is. This understanding was further enhanced by additional understanding of protein function, binding and folding.

Lung diseases and all its contributors is an area of pathophysiology that encapsulates this process. Few organ systems are as impacted by environmental, infectious and perhaps genomic influences as the respiratory system. This chapter will discuss the genomics of lung diseases, concentrating on several major lung disease states: Acute

Lung Injury (ALI), Chronic Obstructive Pulmonary Disease (COPD)/Asthma, pulmonary hypertension and interstital lung diseases. There will also be a brief discussion on computational biology and complexity theory and how it relates to understand disease states.

GENOMIC NOMENCLATURE AND INVESTIGATIONAL TOOLS

To describe and present data on genomic studies, there needs to be consistent nomenclature and definitions. Few definitions are discussed below that will be used in this chapter.

Allele: Alleles are Deoxyribonucleic Acid (DNA) sequences at the same physical gene locus, which may or may not result in different phenotypic traits.

Bioinformatics: The science of applying computational tools to search databases, analyze DNA sequence information, and to predict protein sequence and structure from DNA sequence data.

Haplotype: A set of closely linked alleles inherited as a unit.

Homology: Genes derived from a common ancestor.

Locus (loci): Position on a chromosome of a gene or other chromosome marker (can also be the DNA at that position).

Microarrays: This is a technology that allows the high throughput analysis of multiple genes from a single sample. The technology is based on probes, which are immobilized in an ordered two-dimensional pattern. Probes are either spotted cDNAs or oligonucleotides and are designed to be specific for an organism, a gene or a genetic variant.

Polymerase chain reaction (PCR): It is a method for synthesizing millions of copies of a specific DNA sequence.

Single-nucleotide polymorphism (SNP) (Polymorphism): A SNP is a DNA sequence where a single nucleotide in the genome differs between members of a species.

Genomic Research

Since the beginning of high throughput genomics, there has been a tendency to single out small number of genes and make claims regarding the contribution of genes towards a particular disease state. This has been dubbed the reductionist approach and is more in line with the standard research paradigm.[2] It rapidly became clear that gene expression does not always translate to protein production or functionality. More recent research paradigms have focused on a system approach looking at the groups of genes and evaluating these groups as a part of a system involving single or multiple pathways. This approach has been enlightening and has generated a better understanding of host-gene-protein interactions and probably more of a "real world" picture.

Genomics and Acute Lung Injury

Acute lung injury is not a homogeneous disease as once thought. ALI can be related to a primary lung insult, such as aspiration or related to a process or distal to the lung such as pancreatitis. This has resulted in rethinking ALI, either as a primary process in which the injury is an epithelial-to-endothelial process, or a secondary process in which the insult is endothelial-to-epithelial. Both disease types are phenotypically similar, but may have very different morphologic response of the lung itself.[3] Although the etiology remains unclear, there does appear to be an imbalance between pro- and anti-inflammatory cytokines; oxidants and antioxidants; procoagulants and anticoagulants; neutrophil activation and neutrophil clearance; or proteases and protease inhibitors.[4] We will limit our discussion of what is felt to be the more significant proteins, involved in the development of ARDS.

Angiopoietin-2 (Ang-2) is a potent regulator of vascular permeability and inflammation in acute lung injury and acute respiratory distress syndrome.[5] This protein aids in promoting the cell to cell integrity and maintenance of gap junctions. Several studies have demonstrated that the high levels of Ang-2 are associated with ARDS related to primary lung injury and secondary lung injury,[6,7] VILI and hyperoxia related to ALI.[8]

Genomic studies have demonstrated differing gene expressions in animals with ALI induced by differing mechanisms. In one study, rats with ALI induced by LPS and others by high-volume ventilation were compared.[9] Microarray expression analysis revealed the different expressions of genes based on biological function between the groups. Genes that showed increased expression in the LPS group were metabolism, defense response, immune cell proliferation and cell death. Those with ALI induced by volutrauma were organogenesis, morphogenesis, cell cycle, and cell proliferation and differentiation. This supports the concept that ALI is really a downstream process, or phenotype, with many different genotypic avenues leading to the injury.

TABLE 4.1: Numerous genes, reported to be associated with ALI, listed by the gene symbol, gene name and the associated genetic variant

Gene symbol	*Gene name*	*Associated variant*
IL-6	Interleukin-6	Gene-wide haplotypes G/C-174
TNF	Tumor necrosis factor	G/A -308
VEGF	Vascular endothelial growth factor	C/T +938
IL-10	Interleukin-10	A/G - 1082
MIF	Macrophage inhibitory factor	Haplotypes
ACE	Angiotensin converting enzyme	I/D intron 16
NFkB	Nuclear factor kB	Ins/del ATTG -94
SFTPB	Surfactant associated protein B	T/C +1580 Intron 4TR
MLB2	Mannose-binding lectin	3 variant at multiple haplotypes Gly54Asp
CXCL2	Interferon-gamma-inducible protein	-665 TR

These studies, however, are greatly limited by phenotypic differences, incomplete gene penetrance and gene-environmental interactions.[10] All of that is further complicated by the different populations investigated and the degree of heterogeneity. Many genes have been associated with ALI (Table 4.1).

Polymorphism has also been demonstrated to be a variable in the development or response to ALI. In a study, the European descendents with ARDS were found to have an insertion/deletion polymorphism of the NF-κB promotor; those that were homozygous for the deletion of this promoter had higher lung injury scores, but no change in the outcome.[11] Similarly, the 4G/5G polymorphism of the plasminogen activator-1 gene has been shown to prolong ventilation in patients with pneumonia and ALI.[12]

Heme oxygenase-1 appears to offer cytoprotection to the development of ALI. The haplotype S-TAG of the heme oxygenase-1 gene is associated with an increased ARDS risk. In a somewhat different twist, the longer the repeats of the (GT) allele of the heme oxygenase gene, the higher were the heme oxygenase serum levels, which resulted in reduced risk of developing ALI.[13]

The list of genomic variables will expand over the next few years with each SNP or significant gene being promoted as a target of therapy or marker of disease. It is, however, a simplistic view that a “magic bullet” will be found using high throughput genomics. Genomics are extremely complex with gene-to-gene interaction, gene-to-environment interactions and varying penetrance, all confounding the data. Although bioinformatics has come a long way in accounting for these variables, the level of complexity is far beyond from our current understanding. Genetic studies that investigate disease states must account for population heterogeneity. Understanding this heterogeneity will be paramount, before any meaningful data can be conjectured or therapeutic interventions advanced.

Genomics and COPD/Asthma

Chronic obstructive pulmonary disease is a very complex disease state with both gene-environmental interactions and genetic susceptibilities. A recent study compared gene expression and SNPs in over 300 patients with COPD that had rapid decline in FEV$_1$ to those that had a lesser degree of decline.[14] Till date, these investigators have isolated over 50 genes that are differentially expressed (Table 4.2).

TABLE 4.2: Some of the major candidate genes that are differentially expressed in COPD

a1-AT Z2,
Arg139,
β2AR
Glu27 > Gln0.6,
Haplotype-IL1RN A1/IL1B ,
IL8 A,
IL6,
MMP-1,
IL4RA2
Glutathione Transferases (GSTP1 Ile105 > Val, GSTT1and GSTM1),
Heme oxygenase-1,
Catalase1Nicotine Receptor (CHRNA5)

Table key: a1-ATZ = heterozygosity for the Z allele of alpha one antitrypsin; mEH = microsomal epoxide hydrolase; β2AR = the beta 2 adrenergic receptor; IL1RN A = interleukin 1 receptor antagonist; IL8 = interleukin 8; IL6 = interleukin 6; MMP-1 = matrix metalloproteinase 1; IL4R = interleukin 4 receptor; glutathione transferases (GSTP1, GSTT1 and GSTM1); heme oxygenase-1; catalase; and the nicotine receptor (CHRNA5)

Genome wide analysis of patients with COPD was performed in 7,691 participants in the Framingham Heart Study.[15] Four SNPs on chromosome 4q were strongly associated with FEV1/FVC and one of these SNPs was also associated with FEV_1/FVC in the Family Heart Study and a similar Norwegian study.[16]

Recent studies identified 200 oxidative stress-related genes that were differentially expressed in the bronchial airways between smokers with and without COPD.[17,18] Looking at genome expression of the airway epithelium demonstrates that smoking exposure produces epithelial gene expressions that are specific for this exposure[19] and are associated with tobacco-related lung cancers.[20]

It is clear that the lung and epithelium of the lungs show differing genomic expressions in COPD progression and tobacco exposure. Even correlating some of these genes to eventual cancer development is an exciting advancement. However, like all genomic studies, there are limitations and cautions that must be observed when making broad conclusions. Even though genes may be expressed, this may not translate into protein synthesis or protein function. Therefore, proteomic studies are also needed to complement the genomic studies. With these tools in hand, investigators can shed new light in the understanding of the pathology of COPD especially on a molecular level.

A recent study by Lee et al,[21] preformed "shotgun" protein analysis of lung tissue and epithelium of patients without COPD, smokers without COPD and COPD that had ongoing tobacco exposure. They found twelve proteins that were differentially expressed. Of the twelve, matrix metalloproteinase (MMP-13) and thioredoxin-like 2 were significantly increased in the COPD patients. MP-13 was isolated mainly in the alveolar macrophages and type II pneumocytes with thioredoxin-like 2 was primarily seen in the bronchial epithelium.

There is far less data in asthma and genomic variability. Although there is obvious inheritance of allergic tendencies, less is clear about individual variation of patients with asthma; however, this is rapidly changing. One of the first steps has been the improved identification of the phenotypes of asthma. A recent study looking at hierarchal clustering analysis of 628 variables on 726 subjects found five subgroups (clusters) that were identified.[22] The clusters were:

***Cluster 1*:** Early onset atopic asthma with normal lung function treated with controller medications and minimal health care utilization.

Cluster 2: Early onset atopic asthma and preserved lung function, but increased medication requirements and health care utilization.

***Cluster 3*:** Older obese women with late onset nonatopic asthma, moderate reductions in FEV_1 and frequent oral corticosteroid use to manage exacerbations.

***Clusters 4*:** Severe airflow obstruction with bronchodilator responsiveness.

Clusters 5: Have severe airflow obstruction with bronchodilator responsiveness and use of oral corticosteroids.

This classification system may provide better categorization in order to apply genomic investigations.

Some genome comparisons have been performed, but usually have identified extreme differences in gene expression. As the sophistication of bioinformatics has developed, less robust gene expression changes can be found and may add to the ever increasing list of genetically determined phenotypes of asthma.[23]

In spite of the limitations to genomic studies in a disease process that affects different genetic pools, several genes have emerged consistently across diverse populations. The major genes are TNF alpha, IL4, FCERB, Adam 33 and $GSTP_1$.[24] Also, polymorphisms of the chemokine receptor-2 (CCR2) have been found to be present in asthma and may play a significant role in disease susceptibility.[25] A large cohort analysis identified a locus containing DENND1B on chromosome 1q31.3 that was associated with susceptibility to asthma.[26] This locus was found in children with both European and African descent.

More recent genomic investigations have begun to diverge from pathophysiologic variability and to look at therapeutic variability. Much of the attention has focused on the beta2-adenergic receptor (BDRB2). Although there are polymorphisms identified with this gene, there is also a question as how it may affect therapy with β-agonist.[27,28] It is likely that all therapies have potential for genetic variability in responsiveness[29] and this is why, pharmacogenomics is such an important field in the future of asthma therapy.

Genomics and Interstitial Lung Disease

Interstitial lung disease is a heterogeneous group of diseases that have eluted etiologies. Diagnostic classifications have been made, based on clinical course, high-resolution CT scan and pathologic tissue examination. There have been high hopes that genomics would hold promise as a diagnostic tool, particularly in early disease.[30]

Sarcoidosis

This is an inflammatory lung disease that has demonstrated altered BAL fluid with proteins that are not from leaked plasma.[31] Many of these proteins are not surprisingly related to inflammation. Many genomic studies have been able to narrow these proteins to the inhibitory nuclear factors kappa B-alpha (IκB) and nuclear factor kappa B (NFκB). Polymorphisms of the IkB promotor have been shown to be associated with sarcoidosis, with the -297T allele carriage. This was found to be more prevalent in patients in comparison to the control groups. Three common haplotypes were found, of which haplotype 2 (GTT) was most commonly associated with sarcoidosis. Subgroup analysis revealed that the -826T allelic carriage was most prevalent in stage II and III disease.[32] In high throughput genomic analysis, genes that were found to be associated with persistent disease included HLA-DRB1*1501, DQB1*0602, TNF-α, NFkB, cyclic AMP-responsive element modulator (CREM) and T-cell activation marker CD69. Those associated with self-limited disease included IL-1B, IL-8, growth related (GRO)-beta/-gamma and CCR 2,5,6.[33]

Usual Interstitial Pneumonia (UIP)

Usual interstitial pneumonia/idiopathic pulmonary fibrosis is the severest form of idiopathic interstitial pneumonia. The cellular make up is diverse and therefore the genomics of the disease is very descriptive of disease-related genomic complexity. In a study by Kelly et al,[34] genomic expression studies were performed on differing cellular matrix of UIP lung samples. They compared fibroblast, epithelial cells and type 2 pneumocytes. Using QT-PCR, they found that the tissue inhibitor of matrix metalloprotease-1 and matrix metalloprotease-2 gene expression was upregulated within the fibroblastic foci compared with the epithelium. Along with the previously mentioned mRNA, osteopontin was found to be upregulated in fibroblast, epithelial cells and type-2 pneumocytes. Also, levels of Bone Morphogenetic Protein (BMP)-4 antagonist gremlin were found upregulated in IPF/UIP, which seems to correlate with the severity of illness.[35]

UIP again is very complex, with differing states of fibrosis and repair expressing different genes and phenotypes. The phenotype of regenerative epithelium in UIP appears to be derived from bronchiolar basal cells and Clara Cells (CC). In severe fibrotic areas, CC-10 expressing cells were more prominent, while Surfactant Apoprotein (SP-A) positive cells were more prominent in less fibrotic areas.[36] In a case report of a child with UIP-like histology, mutations were found in the adenosine triphosphate-binding-cassette-A3 gene.[37] Its implications are yet to be investigated, but it further demonstrates the complexity of genomic studies, particularly of applying them to the diseased states and unfortunately, translating them into therapeutics.

As for diagnostics, genomic markers may offer diagnostic differentiation among the interstitial lung diseases. For example, the TH1 cells chemoattractant monokine, induced by interferon (IFN)-gamma (MIG) and IFN gamma-inducible protein of 10 kD expression, were significantly higher in NSIP compared with UIP.[38]

Genomics and Pulmonary Hypertension

Pulmonary artery hypertension (PAH) remains an idiopathic process, but there is an emerging data that the disease is multifactoral, multigenetic and environmental. The disease is often subgrouped into idiopathic, familial and assocated PAH. Heterozygous mutations in BMPR2 can be detected in 50% to 70% of patients with familial PAH and in 10% to 40% of patients with idiopathic PAH. Heterozygous or homozygous bone morphogenetic protein receptor type 2 (Bmpr2) deletion in pulmonary endothelial cells predisposes mice to develop PAH.[39] Although initially isolated in familial PAH, its presence without direct inheritance may represent a genetic milieu that promotes the development of PAH in the face of environmental factors and other inducers.[40] In children with PAH, the Activin Receptor-Like Kinase 1 gene (ALK1) has also been found in familial PAH.[41] However, its role and significance in the cases of idiopathic PAH is unknown.

Using a hypothesis generating approach to idiopathic PAH using microarray technology, have revealed a distinct expression profile in peripheral B-lymphocytes. This revealed 33 unique genes, which were differentially upregulated in idiopathic PAH.

The proteomic methods of investigation have shed more light on PAH. The PAH associated with sickle-cell disease cohort has been characterized by the high levels of apolipoproteins A-II and B and serum amyloid A, and low levels of haptoglobin dimers and plasminogen.[42] In a cohort of idiopathic PAH, the proteins Alpha-1-anti-trypsin and vitronectin were found to be down-regulated.[43]

Biocomplexity and Computational Biology

The age of genomics is upon us and has exponentially expanded our understanding of the molecular basis of many diseases, including the ones discussed above. Genomic expression studies often report a significant gene or a group of genes in a disease process. Many times this is based solely on mRNA expression and is not followed through protein translation and function. This

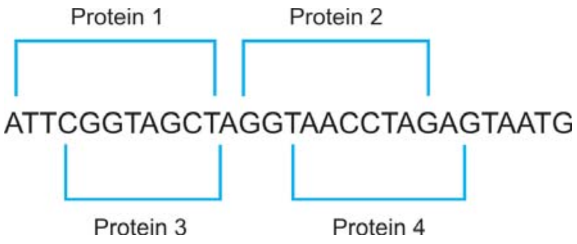

Fig. 4.1: Demonstrating that a specific DNA base pair sequence can represent many genes depending on the starting point and ending point of the transcription. Thus there is crossover among the sequence to produce many different proteins from a relatively small base pair sequence

is too simplicitic as the entire landscape of genomics is changing. We are just beginning to understand that gene-to-gene interactions and gene-to-protein interactions are far more complex than previous thought. Although the basic structure of DNA is eloquently beautiful and simple, that is where simplicity ends.

All of us were taught the genomic paradigm of one-gene one-protein and that a specific gene belongs to a specific chromosome. Now we know that this is not necessarily true. Many genes and DNA sequences can crossover to transcribe different proteins on the same gene. That is to say that a long DNA sequence may transcribe albumin, if started with a specific DNA sequence. If, however, the DNA transcription starts one base pair away, it may transcribe a protease, even though it is still within the albumin gene as shown in Figure 4.1. This means that all the DNA sequences that were once thought to be "junk" genes are a part of this shared-gene concept and is what makes us unique as a species. Only by using the bits and pieces of different genes to make a new gene so to speak, and understanding that the concept of one-gene one-protein is not true, can we explain our diversity. Added over this is the fact that genes seem to have the ability to change chromosomes; this is where we enter the world of complexity theory and the need to use complex computational tools to understand these complex interactions. It is likely that the only way that meaningful therapeutics will emerge from this age of genomics is through these tools.

A study, which identifies a gene that shows upregulation, in no way, translates to functional or phenotypic changes. Even confirming mRNA of the gene or the presence of the translated protein in no way assures that the protein has pathologic or physiologic function. This is one reason why there have been such disappointments in genetic therapeutics. Genomic studies need to be looked at in the context of the host, the environment and heredity to name a few confounders.[44]

This interaction has prompted the new science of biocomplexity and computational biology that evaluates the biologic pathways that generate disease.

New areas of investigations are emerging all the time. For example, looking at the spatial relationships of a nucleosome to the gene and how this relationship may influence function.[45] However, the biggest advance recently appears to be the study of epigenetics.

Epigenetics

Epigenetics is a new field that is shedding new light over many diseases. Epigenetics is the evaluation of phenotypes that are unique to a cell line or species that is not directly related to the base genome sequence.[46] These phenotypes result from non-genetic influences and can persist for several generations. How this affects lung diseases is presently unknown, but deserves considerable attention, particularly since most lung diseases have significant environmental influences. Each of these influences can affect phenotypic expression that cannot be explained by DNA sequences. This may greatly enhance our understanding of genetics and fill many questions about diseases and protein behaviors that are not easily explained by genetics alone.

SUMMARY

Genomics have come of age. Genetic contributions to disease states have moved beyond inheritance. New tools, such as microarrays have provided new insights into diseases, allowed new hypothesis to evolve and have thrust reductionist philosophy into the world of biocomplexity. Lung diseases have always been difficult to study due in part to the numerous influences that foster a disease or exacerbate a disease. Genomics and epigenomics are providing new insights into these diseases that will hopefully produce better diagnostics and therapies.

Applied Respiratory Physics

SK Jindal, VK Jindal

INTRODUCTION

Functioning of the respiratory system is largely governed by the physical principles and laws. Knowledge of simple, applied physics is important to understand the movement of air in and out of the lungs, the flow of blood across the pulmonary vessels, exchange of gases and maintenance of the fluid balance. This chapter provides a brief introduction to the general physics with reference to the respiratory functioning. More details are available in the respective chapters on individual subjects in the book.

STATE OF MATTER

Matter can exist in three classically different forms in nature—solid, liquid or gas; although plasma, a fourth state of matter has also been identified under the extremes of temperature and pressure. Matter is either an element made from similar atoms, e.g. iron or compound made from two or more types of atoms, e.g. water (H_2O) in nature. An element is a basic unit of matter, which retains the same properties on subdivisions by chemical or mechanical means. Oxygen and other gases, such as hydrogen, helium, chlorine and nitrogen are elements in nature.

Atom and Element

An atom is the smallest part of an element, which acts like its "building block". On the further subdivision of an atom, the elemental properties are lost and therefore, subatomic constituents of all atoms are identical. Atoms of certain elements (e.g. hydrogen, helium) can exist in free state (H, He) and there is no difference between the atoms and molecules of these elements. Atoms of many other elements (such as oxygen) do not exist free, but combine with other atoms of the same element to form molecules (e.g. O_2, i.e. O+O). Atoms of different elements may form molecules or compounds. Hydrogen can exist in atomic or molecular form, whereas nitrogen and oxygen occurs in molecular form (N_2 and O_2).

Molecule and Compound

All substances consist of exceedingly small particles called molecules. There are about 10^{19} molecules in 1 ml of air under the normal conditions of temperature (T) and pressure (P). A molecule possesses the distinctive properties of the parent element or compound. A molecule is found to consist of two or more atoms of same kind or of different kinds.

The number of molecules comprising a macroscopic quantity of a gas is enormous typically around 10^{23} molecules. The number of molecules and their velocity determine many properties of gases.

A compound is composed of two or more elements united chemically to form a substance different from the individual elements forming that compound. For example, carbon dioxide is a compound of carbon and oxygen. On subdivisions, the compound loses its properties and may resume those of the constituent elements. Both elements and compounds exist as molecules as the smallest component.

Molecular Movement

All the molecules of matter are in a state of incessant motion. This is known as Brownian movement and forms the basis of the kinetic theory of matter. This motion results from temperature—the higher the temperature, the larger the velocity of the molecules. At absolute zero temperature, the velocity of a classical molecule goes to zero. Molecules of a gas have great mobility and travel longer distances before colliding with other molecules. It is because of this mobility that a gas has no fixed shape and mixes readily with other gases.

Atomic and Molecular Weights

The mass of an atom is concentrated at its nucleus, which contains a definite number of neutrons and protons of identical masses. The neutrons or protons are also called nucleons. The mass of a nucleon is ≈ 1.6 x 10^{-24} gm (sometimes also called atomic mass unit, amu). Therefore, total number of nucleons of an atom determines the mass of an atom and is usually called atomic weight. This H´ atom has atomic weight equaling 1, whereas O´ atom has atomic weight equaling 16. Though their actual masses are around 1 x 1.6 x 10^{-24} gm and 16 x 1.6 x 10^{-24} gm, respectively. Similarly, molecular weight is determined by summing up atomic weights of the constituent atoms forming that molecule. As an example, H_2 molecule has a molecular weight = 2, and H_2O molecule has a molecular weight = 2 + 16 = 18. For obtaining their actual weights, we multiply those weights by amu (= 1.6 x 10^{-24} gm) to get the mass in gm.

If M is the molecular weight of given substance, then 1 molecule of that substance weighs M × 1.6 × 10^{-24} gm. This gives us that M gm of the substance will have 1/1.6 x 10^{-24} molecules, which is called Avogadro number, $N_o \approx 6.02 \times 10^{23}$. It is thus clear that M gm (also called 1 mole) of any substance will have N_o molecules.

Gaseous substance (which behave like an ideal gas) follow an equation PV = nRT

One can easily calculate the volume at NTP (normal temperature 0°C, and pressure ≡ 760 mm Hg) from η = 1 mole. It comes out to be 22.4 liters for any gas. Therefore, a quantity of any substance equaling molecular weight as gm has 6.02 × 10^{23} molecules and as a gas, occupies 22.4 liters at NTP.

Equal volumes of gases at the same temperature and pressure contain equal number of molecules **(Avogadro's Hypothesis)**.

PHYSICAL PROPERTIES OF GASES

The air we normally breathe is a mixture of gases of which oxygen and nitrogen constitute the main bulk. Breathing of additional or supplemental gases is required in abnormal situations. The physical properties of these gases influence the mechanics of normal breathing, as well as the therapeutic strategies.

Volume

Volume is the space occupied by a gas. The volume of a cuboid-shaped vessel is determined by the multiplication of internal length, width and height of the vessel. It is expressed in cubic centimeters (cc), cubic feet or liters (L), etc. (1 L ≡ 1000 cc or mL).

$$\text{Volume} = \text{Length} \times \text{Width} \times \text{Height}$$

A 10 cm cube has the volume equaling 1 L. Volume of a container of uniform cross-sectional area A and height is given by V = A h.

The gas shall occupy the available volume irrespective of the amount (mass) of gas. For example, if a small vessel containing oxygen is emptied in a larger vessel, the entire volume of the larger vessel will be occupied by the same amount of gas (Fig. 5.1).

Mass and Weight

Mass is the bulk or the total mass of number of molecules of the gas. In the above mentioned example, the mass of the gas in two cylinders shall remain the same, although the volume has changed. The number of molecules per

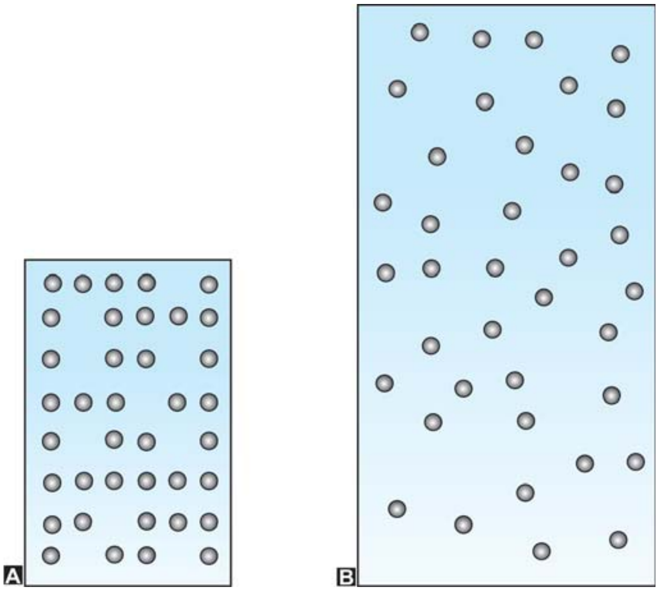

Fig. 5.1: Mass of a gas such as O_2 (i.e. number of molecules) in vessels A and B is unchanged, but the volumes are different therefore, the density of the gas in vessel A is greater than that in vessel B

unit of volume in the two vessels has changed, i.e. lesser number of molecules per unit volume in the larger vessel (Fig. 5.1).

Weight is often used synonymously with mass. Weight is determined by the pull of gravity on mass (i.e. m × g). Since the force of gravity on the earth is nearly constant, mass is equivalent to weight on the surface of the earth. In fact, weight is scaled to indicate mass and therefore both represent the same thing.

$$W \equiv \text{force} = mg$$

Density

Density is expressed as the weight in the grams of one liter of a gas. Since the weight of 22.4 liters of a gas is that of a gram molecule of that gas, one liter of gas shall weigh molecular weight/22.4 gm. When expressed this way, the density will be measured in gm/liter. It is also measured in gm/cc, which will equal 1/1000 in value to that in gm/liter.

Molecular weight of oxygen = 32
Density = 32/22.4
= 1.43 gm/liter

The density of a gas is also expressed as relative to the density of air. Density of air shall vary depending upon its composition. For all practical purposes, it comprises of 1 volume of oxygen (about 20%) and 4 volumes of nitrogen (about 80%). At NTP, the density of air is $(32 \times 1/5 + 28 \times 4/5) / 22.4 = 1.3$ gm/L. Therefore, the density of oxygen relative to that of air is 1.1. When expressed this way, it becomes unimportant, if the density of individual gases was calculated in gm/liter or gm/cc.

Pressure

The gas molecules are always in a state of motion and constantly bombard the walls of the container. The force applied to (or acting upon) a unit area of the wall is called the gas pressure. The closer the molecules, the greater the number, which strikes each unit area and therefore the greater the pressure applied. Also, larger the velocity (or temperature), larger is the impact on the walls, leading to greater pressure.

Gas pressure is generally considered as that of a stationary gas when the pressure exerted is the same at any point in a gas container. The pressure is usually expressed in the millimeters of mercury (mm Hg) or Centimeters of water (cm H_2O) or pounds per square inch (psi). One millimeters of mercury means force on a unit area (1 cm^2) on which 1 mm of height of Hg is placed. The volume of height h cm on unit area is $A \times h = h\ cm^3$ and in mass is hd where d is the density of the liquid. The force on unit area due to this is hdg, which is also the pressure p. Thus p due to a height h of a liquid of density d, p = hdg. The pressure due to 1 mm Hg can be calculated by putting h = 0.1 cm, d = 13.6 gm/cc and g = 980 cm/S^2.

1 mm Hg ≡ 1334 CGS units or dynes/cm^2
= 133.4 Pa (Pascal is another unit of pressure)

Atmospheric Pressure

Atmospheric air is pulled to the earth by gravity and generates a force upon the surface of the earth, resulting in atmospheric pressure. Atmospheric pressure is the sum of pressures of all gases (e.g. N_2, O_2 and CO_2) present in air). It is measured with the help of a glass tube filled with either mercury or water (manometer). The height of the column of mercury (or water) multiplied by its density is a measure of the atmospheric pressure. Standard pressure is measured at sea level and expressed in mm Hg (torr) or cm H_2O. One atmospheric pressure = 760 mm Hg or
14.7 psi or
1030 cm H_2O

It is important to convert atmospheric pressure (≡ 76 cm of Hg) in CGS units. This is approximately 10^6 CGS units.

$$1 \text{ atm} \equiv 76 \text{ cm of Hg} \simeq 10^6 \text{ CGS} \simeq 1 \text{ bar}$$

It is relevant here to mention that the lungs are subject to atmospheric pressure all the time. Since the alveoli are in direct communication with the atmosphere through the tracheobronchial tree, the alveolar pressure is the same as the atmospheric pressure. The changes in alveolar pressure during inspiratory and expiratory phases of respiration are relative to the atmospheric pressure. During inspiration when the alveolar pressure is –10 cm H_2O, it implies the presence of atmospheric pressure—10 cm H_2O (i.e. 1030 – 10 cm H_2O). Similarly, when positive pressure is administered to a patient through a ventilator, the ventilator gauge pressure of 10 or 20 cm H_2O refers to a total pressure of 1040 or 1050 cm H_2O (i.e. atmospheric pressure + gauge pressure).

Partial Pressure

In a mixture of gases in a container, each gas exerts the same pressure, which it would if it alone occupied the container. There is no interference from the presence of other gas(es). The pressure exerted by each individual gas is called the partial pressure. The total pressure exerted by the mixture of gases is equal to the sum of the partial pressures of all the gases contained in the mixture (Dalton's law). The partial pressure is determined by the fraction of the concentration of the gas in the mixture.

The atmospheric air has a total pressure of 760 mm Hg when dry at sea level. The partial pressures of N_2 (79%) and O_2 (21%) therefore, are as follows:

P_{N_2} = 79% of P_{atm} = 600.4 mm Hg
P_{O_2} = 21% of P_{atm} = 159.6 mm Hg

Temperature and Heat

Temperature is the thermal state of a substance, which determines whether the substance will give or receive heat from another substance in contact. It is an indication of the level of molecular activity. Heat is the thermal energy of a substance, which can be given to or abstracted from it. Temperature is the measurement of heat.

Calorie is the unit of heat. It is defined as the quantity of heat required to raise the temperature of 1 gm of water by 1^{o}C. As an example, if one calorie is required to raise the temperature of 1 gm of water by 1^{o}C, 1000 calories will be required for 1000 gm of water. The caloric value of food is expressed by a larger heat unit, i.e. the kilocalorie (cal or kcal), which is equivalent to 1000 cal.

To raise the temperature to a given range, similar weights of different substances require different quantities of heat. The number of calories required to raise the temperature of 1 gm of that substance by 1^{o}C is the specific heat of that substance.

The specific heat depends on the state of the matter—solid, liquid or gas. Specific heat of water is 1 (It follows from the definition of 1 calorie).

For gases, such as O_2 and air, it is 0.0603 cal per cc, it is quite high when expressed per gm.

We can calculate the total quantity of heat required to raise the temperature of a given volume by multiplying the volume with specific heat and temperature rise, i.e. volume (cc) × specific heat (cal per cc) × temperature rise (^{o}C).

THE GAS LAWS

There is a definite relationship between the gas properties described above. These relationships are described in different laws to understand the behavior of gases. These laws are valid for ideal gases only, where the assumption that the gas particles are very small and do not interact with each other is valid.

Boyle's Law

Pressure (P) of a gas is inversely proportional to its volume (V) provided the absolute temperature (T) of the mass of gas is kept constant. In other words, the product of pressure and volume remains constant. It follows immediately from the ideal gas equation,

$$P \propto \frac{I}{V} \text{ or } P \times V = \text{constant, if T is constant.}$$

Or $P_1 V_1 = P_2 V_2$

The application of this law in respiratory physiology is best exemplified in the use of body plethysmography to measure total lung capacity. It is also employed in many mechanical ventilators whereby the gas is driven into patient's lungs or into the cylinder of the ventilator by the upstroke and downstroke movements of the piston.

Charles' Law

When pressure and mass of a gas are kept constant, the volume of the gas will vary directly with its absolute temperature. Again from gas equation,

= Constant (K), if P is constant

It is because of this reason that volumes measured with the help of lung function equipments (at room temperature) are a little lower than those at body temperature (37^{o}C) and need to be corrected for the same. If the temperature of a container of a gas is lowered, the volume shrinks. Therefore, more gas can be stored in the same cylinder at a lower temperature.

Gay-Lussac's Law

Temperature and pressure of a gas are directly proportional when the volume and mass are kept constant.

$P \propto T$ or = K at constant V

It implies an increase in pressure if the temperature is increased. For this reason safety valves are provided with devices using high pressure gases to vent high pressures in case there is an accidental heating.

The General Gas Law

Assume N ideal noninteracting molecules of a gas each of mass m are contained in a cube of volume V. They are in motion if the temperature is above 0^{o}K (0^{o}K = -273^o C). If the temperature is T in Kelvin, the kinetic energy from each molecule is of the order of kT, where K is called Boltzmann constant (K = 1.38 X 10^{-16} CGS units). Because of this kinetic motion, the molecules of the gas keep bombarding the walls of the cube and exert pressure. The pressure increase results in extra energy (obtainable from force X distance or p x volume relation). In this way it is quite evident that one can equate the energy because of pressure PV as resulting from kinetic energy of N molecules, PV = NkT.

If N is expressed in N_o (Avogadro No.), PV = η N_okT, where η = N/No.

This is the famous gas equation valid for all ideal gases. η is the number of moles of the gas, N_ok is also called gas constant R. R $\simeq 6 \times 10^{23} \times 1.38 \times 10^{-16}$ erg/deg K

$$\simeq 2 \text{ cal./deg K}$$

The gas equation can be used to determine how the given initial state (P_1, V_1, T_1) relates to (P_2, V_2, T_2), some final state by using P_1V_1 ($T_1 = P_2V_2/T_2$).

$$\frac{P_1 V_1}{T_1 n_1} = \frac{P_2 V_2}{T_2 n_2}$$

It may be stated here that under the conditions of lower temperature and high pressure the gas changes its state to liquid. This is because the gas molecules get attracted to each other (van der Waals forces) rather than being repelled. The higher pressure condenses the molecules and the lower temperature reduces their activity.

$$\frac{D_1}{D_2} = \frac{d_2}{d_1}$$

$$\frac{1.3}{1000}$$

The temperature at which the gas turns into liquid is the "critical temperature" of that gas. For oxygen, it is -116°C. A pressure of 50 atmospheres is required to liquefy oxygen at –116°C. To keep the oxygen in a liquid form at 1 atmosphere in a flask open to the atmosphere, the temperature is lowered to below-183°C. This principle forms the basis of the availability of oxygen in the liquid form for storage and ambulatory use.

Henry's Law

The amount of gas that enters into physical solution in a liquid is directly proportional to the partial pressure of the gas. For example, the greater the partial pressure of oxygen in the alveoli, the greater the solubility in plasma.

Graham's Law

The rate of diffusion (D) of a gas is inversely proportional to the square root of its density (d).

Therefore, a light gas (such as helium) will diffuse at a faster rate than a heavier gas (such as oxygen).

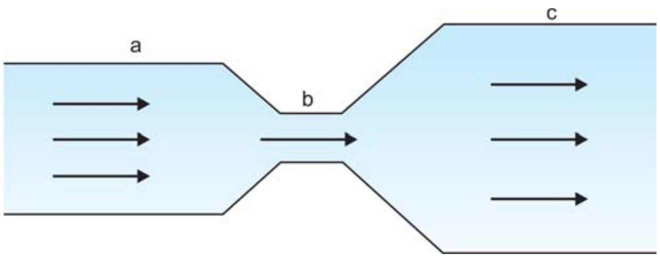

Fig. 5.2: Bernoulli's principle

Bernoulli's Principle

Flow of a gas through a partially obstructed tube can be described by Bernoulli's principle, i.e. the pressure required to produce flow is the difference in velocity at two points and the density of the gas (Fig. 5.2).

GAS SOLUTION AND TENSION

The amount of gas dissolved in a liquid is directly proportional to the pressure of the gas (Henry's law). It also varies with the temperature—lesser amount is dissolved at the same pressure if temperature is increased. A state of equilibrium is reached when no further gas dissolves in the liquid. This is a state of full saturation with the gas at a given temperature and pressure. The gas in solution is said to exert the same "tension" as the partial pressure of the gas over the liquid in equilibrium with it. For example, when the partial pressure of oxygen in alveoli is 100 mm Hg, the tension of O_2 in alveolar capillaries is 100 mm Hg. At this pressure, 0.3 cc of oxygen at NTP dissolves in 100 cc of water. The weight of oxygen dissolved in 100 cc water is

0.3 × = 0.0004 gm (1.3 gm/L is the density of oxygen).

The amount of oxygen dissolved in plasma or water is the same (0.004 gm/100 ml). This is quite sufficient to supply all the oxygen necessary for the metabolism of the body.

VAPORS

Vapor is defined as the gaseous state of a substance, which at room temperature and pressure is a liquid. On the other hand a gas at room temperature exists only in the gaseous state. Like any other gas, the molecules of a vapor are continuously in violent motion and bombard the walls of the container. The force exerted on each unit area is called the pressure of the vapor **(Vapor Pressure)**.

A vapor in a mixture of gases obeys the same laws as the gases. The partial pressure of the vapor in a mixture bears the same proportion to the total pressure as the volume, i.e. it depends on the percent (or fractional) concentration in the mixture. For example, the concentration of about 16% of water vapors in air at NTP, which is sufficient to saturate air with water vapors exerts a pressure of 16% of 760 mm Hg (47 mm Hg).

The presence of water vapors in air or oxygen is referred to as **humidity**. It is largely through the process of evaporation that the molecules of water (or any other liquid) evaporate into the overlying air (or any other gas in a container).

The molecules leave the liquid substance when their kinetic energy exceeds the surface tension of the liquid. If a liquid is kept in a closed container for long, a state of equilibrium is reached when the number of molecules returning to the liquid **(condensation)** is exactly equal to the number leaving it **(evaporation)**. This is called the saturation-point. This is further dependent upon temperature; if the temperature increases, the number of molecules leaving the liquid also increase and the saturation point is raised, i.e. there is a greater amount of vapors in the same amount of gas. Reverse happens with a fall in temperature.

The air we breathe is normally humid due to the presence of water vapor. The actual amount of water vapor present in air is expressed as "relative humidity", which is defined as the ratio of the amount of water vapor present in a given volume with the amount of water vapor, which the air (or the gas) is capable of holding at the given temperature, in the same volume.

The humidity of air varies with the atmospheric conditions. Once inhaled in the lungs, air gets fully saturated. The amount of water vapor required to saturate the alveolar air at body temperature and pressure is the body humidity.

The presence of water vapor in the inhaled air exerts its own partial pressure, and lowers the pressures of constituent gases of air—oxygen and nitrogen. Therefore, PN_2 or PO_2 is calculated as a proportion of the atmospheric pressure minus water vapor pressure, i.e. $P_{atm} - P_{H_2O}$.

When fully saturated, P_{H_2O} of atmospheric air is equal to 47 mm Hg. Therefore, $PO_2 = (P_{atm} - P_{H_2O}) \times 21\% = (760 - 47) \times 0.21 = 150$ mm Hg. The rest, i.e. 760 – (150 + 47) would be approximately the PN_2.

EXPRESSION OF GAS VOLUMES AND PRESSURES

In view of the effects of temperature, pressure and humidity on all gases, these are expressed with reference to those conditions. Some of the common expressions are:

i. Standard (or normal) temperature and pressure (STP) or NTP
   Temperature 0ºC; Pressure 760 mm Hg.
ii. STPD: D indicates "dry" = complete absence of water vapor.
iii. Ambient temperature and pressure—dry or saturated (ATPD or ATPS). Ambient implies the room conditions.
iv. Body temperature and pressure saturated (BTPS): Body temperature (usually 37ºC), ambient pressure and water vapor pressure (47 mm Hg).

Normally, gas volume measurements are made in the ambient conditions. Conversion is required to express the volume at BTPS or STPD. STPD is used for the uniformity of expression. This is done by multiplying with conversion factors. Tables of conversion factors from ATPS to STPD, STPD to BTPS, or BTPS to ATPS are available in most laboratories. Such corrections are also required to express volume of a gas (such as O_2) produced in the laboratory. The volume is expressed at STPD, which is different than that produced at ATPS.

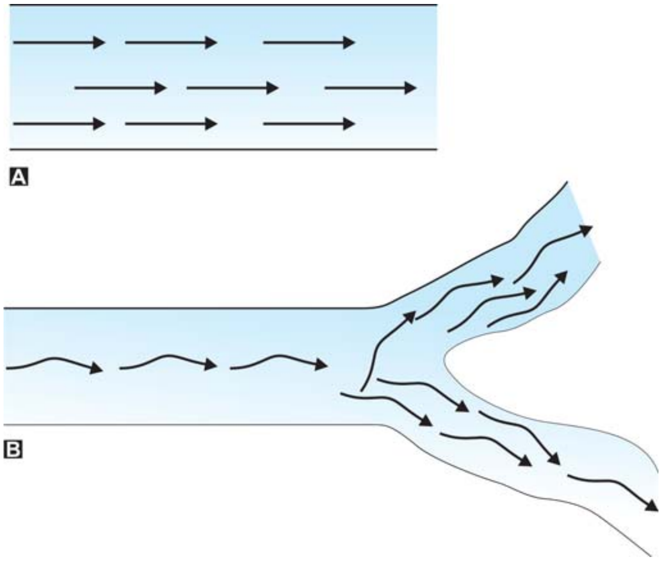
FLOW OF GASES

Flow is the movement of particles of a liquid or a gas from higher to lower pressure. It is expressed in the terms of volume per unit time, e.g. liters per minute or per second (L/min or L/sec). The movement of air into the lungs during inspiration and out into the atmosphere during expiration is accomplished by the flow of air through tracheobronchial tree. Similarly, oxygen flows from a container cylinder to the lungs or a ventilator through connecting tubes as long as there is a pressure difference.

The flow is described as laminar, if it is smooth and gas particles move along lines parallel to the walls of the tube (Fig. 5.3A). But it is turbulent if the lines of flow are irregular, broken up and disorderly (Fig. 5.3B). Whether the flow is laminar or turbulent, it has to meet a certain resistance while moving from one to the other end of the tube. The laminar flow is described by the **Hagen-Poiseuille equation**, i.e. $V = \prod \gamma^4 \Delta P)/(8\eta l)$.

Resistance

Resistance is defined by the pressure difference under given conditions, between the entry and the exit points of a tube. The resistance is dependent on the tube length (l) and diameter. It is also directly proportional to the



Figs 5.3A and B: Patterns of flow: (A) Laminar flow, (B) Turbulent flow

velocity of flow (∇) or rate in case of laminar flow. The flow is also viscosity (η) dependent and density-independent. When the flow is turbulent, the resistance rises for steeply.

In this way the laminar flow through a straight tube of uniform size is inversely proportional to the length (l) of the tube and directly to the fourth power of radius (r).

When the flow exceeds a "critical flow rate", the laminar flow is replaced by the turbulent flow throughout the length of the tube. Turbulent flow is less efficient since the ∇ P varies directly with V^2. Turbulent flow is density dependent and viscosity-independent. The critical flow varies directly with the internal diameter of the tube—the larger the diameter, the greater the flow. At a flow below the critical rate, local turbulence may occur as a result of irregularities in the pathways of the gas. During oxygen administration this may occur due to the constriction of kinking of the tubes.

Turbulence in a flowing system can also be predicted by Reynold's number. It is the ratio between inertial (density dependent, viscosity independent) and viscous (viscosity dependent, density independent) forces—a dimensionless number.

In case of pipes,

$$\textbf{Reynold's Number} = \frac{\text{Density} \times \text{Velocity} \times \text{Diameter}}{\text{Viscosity}}$$

Flow is "laminar" when the number is less than 2,000 and "turbulent" when it is more than 3,000. Turbulent flow is dominated by inertial forces producing random eddies and flow fluctuations. Between 2,000 and 3,000, the flow is transitional, i.e. neither fully laminar nor fully turbulent.

Flow Through Orifices

An orifice is a narrow opening of a tube. Unlike a tube, the diameter of the fluid pathway of the orifice exceeds the length. The greater the diameter compared to the length, the more does the opening approach the "ideal" orifice. The flow through an orifice depends on the diameter (or the cross-section area) of the orifice and the difference in pressures on either side of the orifice.

The intrinsic property of a liquid that influences its flow, which we earlier termed as resistance is called viscosity. It is attributed to the internal friction between different layers, which move at different speeds. While the laminar flow largely depends on viscosity, it is the density, which determines the flow when turbulent. The coefficient of viscosity is equal to the force per unit area necessary to maintain the unit difference of velocity between two parallel planes.

The flow through an orifice is at least partially turbulent. The lower the density, i.e. the lighter the gas, the greater is its volume flow for any given pressure difference on the either side of the orifice.

Wave Speed

Wave speed (c) is the speed at which a small disturbance (wave) travels in a compliant tube filled with a gas. In the airways, it depends upon the cross-sectional area of the airway (A). The density of the gas (p) and the slope of the pressure area curve of the airway (dP/dA):

$$c^2 = \frac{A/p}{dP/dA}$$

Maximum flow (V_{max}) of a gas in an airway is the product of the gas velocity at wave speed and the airway area (cA). It increases as the density of the gas decreases.

Thermal Conductivity

It is a measure of a substance's capacity to conduct heat. The high thermal conductivity is likely to result in a higher skin heat loss. But respiratory heat loss depends on heat capacity not conductance.

Heliox

Heliox is a mixture of oxygen with helium (He) in varying concentrations, commonly as 20% oxygen and 80%

helium. It has a lower density than that of air, i.e. oxygen (21%) with nitrogen (79%). Resistance offered to the flow of heliox is lower than that of air and of oxygen and depends on the fractional concentrations. It diffuses 1.8 times faster than oxygen. This fact is exploited in clinical practice for the treatment of acute respiratory distress of obstructive airway diseases, such as asthma when the flow is highly turbulent. Heliox diffuses fastly than oxygen through partially obstructed airways. In view of the lower resistance offered to heliox, the breathing effort is considerably reduced and the crisis tide over.

Diffusion

The molecules in a fluid (liquid or gas) unlike in a solid, move freely in all directions. The time taken by a molecule to travel a given distance depends upon its closeness to other molecules, and the intermolecular spaces. The gas molecules do not necessarily collide with the neighboring molecules when they move around or across a membrane.

Diffusion across a membrane is determined by the difference in concentrations between the two neighboring layers of the solution. The rate of diffusion is proportional to the gradient of concentration, i.e. the change of concentration per unit length in the direction of diffusion **(Fick's law)**.

Diffusion also depends on molecular movement. The rates of diffusion of gases at similar partial pressures through a porous membrane are inversely proportional to the square roots of their molecular weights **(Graham's law)**. The molecular weight of oxygen and CO_2 being 32 and 44 respectively, the diffusion ratio will be 1.2.

$$\frac{\text{Diffuse rate of Oxygen}}{\text{Diffusion rate of } CO_2} = \frac{1.2}{1}$$

It implies that oxygen diffuses 20% faster than CO_2 through a dry, porous membrane. It is because of the solubility of CO_2 in water of the moist alveolar membrane that the CO_2 diffusion is higher than O_2.

Solubility: Another factor, which determines diffusion across a wet film is the solubility of the gas. The rate of diffusion is directly proportional to the solubility of the gas in the fluid.

Permeability: A membrane is permeable, if it allows the particular molecules to pass through, i.e. across the membrane. Permeability of different membranes to the molecules of different substances (solid, liquid or gases) is variable.

Osmosis: Osmosis is the migration of molecules of a solvent across a membrane. The pressure, which stops the transfer of molecules is called the osmotic pressure of the solution. The osmotic pressure of a solution depends only on the number of dissolved particles per liter and not on the nature of the substances, which is dissolved.

The diffusion mechanisms also depend upon the pressures, volume and filtration. In respiratory system, the diffusion of gases and fluids across the alveolar membrane are critically important for normal gas-exchange functions of the lung and in the maintenance of a fluid balance (Some of these issues are discussed in Chapter 7).

Respiratory Function and Mechanics

D Gupta, R Agarwal, AN Aggarwal

INTRODUCTION

Oxygen is essential for the continuation of life. It is required by each human cell for its survival. It is abundantly present in the atmosphere and maintains a remarkably constant concentration of 20.9% in ambient air. Oxygen is taken up by the lungs through the act of inspiration and transported to the cells via blood. At the cellular level, oxygen is utilized for the production of energy. In this process, carbon dioxide is released and transported back via the blood to the lungs from where it is expired out into the atmosphere. The act of the exchange of oxygen and carbon dioxide is called respiration. For effective respiration, air must be drawn through the airways and distributed among approximately 400,000,000 alveolar compartments within the lung parenchyma. Although respiration is normally described as the uptake of oxygen and release of carbon dioxide by the lungs, it is essentially happening at the level of lungs ("external" respiration), as well as the tissues ("internal" respiration).

The respiratory system is made up of a gas exchanging organ (the lungs) and a pump that ventilates the lungs. The pump consists of the chest wall and the respiratory muscles, which increase and decrease the size of the thoracic cavity; the areas in the brain that control the muscles; and the tracts and nerves that connect the brain to the muscles. At rest, a normal human breathes 12-15 times a minute. About 500 ml of air per breath, or 6–8 L/min, is inspired and expired. This air mixes with the gas in the alveoli, and, by simple diffusion, O_2 enters the blood in the pulmonary capillaries while CO_2 enters the alveoli. In this manner, 250 ml of O_2 enters the body per minute and 200 ml of CO_2 is excreted.

Gas exchange by the human lungs is achieved with the help of four processes (Fig. 6.1), which are also variably interdependent:

1. *Ventilation:* To and fro movement between the atmosphere and the gas exchanging units of the lung.

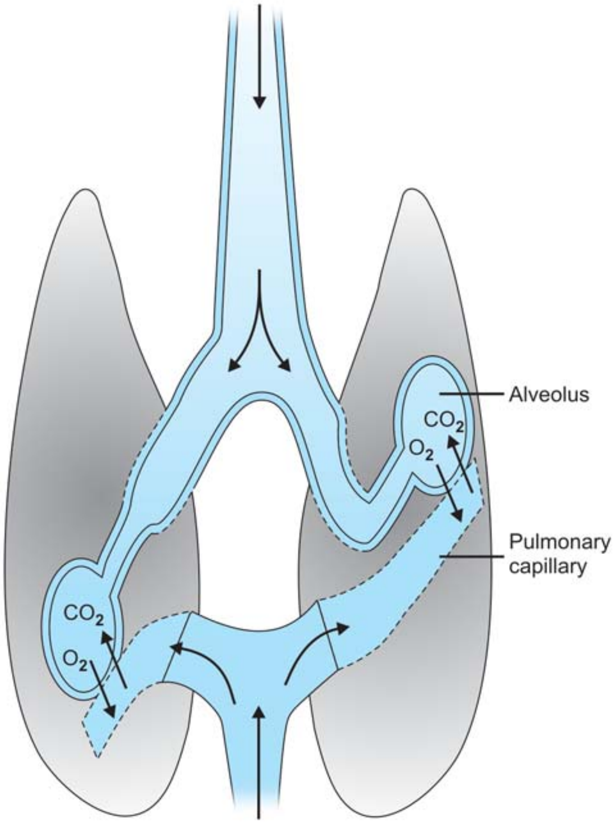

Fig. 6.1: Schematic diagram to represent different processes involved in respiration

2. *Circulation:* Supply and distribution of blood through the pulmonary capillaries.
3. *Diffusion:* The movement of O_2 and carbon dioxide across the air-blood barrier between the alveoli and the pulmonary capillaries.
4. Ventilation-perfusion relationships.

VENTILATION

Ventilation is the process of bulk movement of air from atmosphere, through the conducting airways to the terminal respiratory gas exchange units. This movement of air is made possible by the force which is generated by the effort of respiratory muscles (or a mechanical ventilator if the patient is being ventilated). Obviously, it is also dependent on the mechanical properties of the conducting airways and the lung parenchyma (i.e. the breathing units). The mechanical properties are referred to as "static" at zero (or no airflow) flow and constant volume, and "dynamic" if there is airflow.

The amount of air that moves in and out of the lungs with each inspiration and expiration respectively is called the tidal volume. The air inspired over and above the tidal volume with a maximal inspiratory effort is the inspiratory reserve volume, and the volume exhaled actively after passive expiration is the expiratory reserve volume; the air left in the lungs after a maximal expiratory effort is the residual volume. The respiratory dead space is the space in the conducting zone of the airways occupied by gas that is not involved in gas exchange. The vital capacity, the largest amount of air that can be exhaled after a maximal inspiratory effort, is a frequently measured index of pulmonary function. The fraction of the vital capacity exhaled during the first-second of a forced expiration is the FEV_1. The maximal voluntary ventilation is the largest volume of gas that can be moved into and out of the lungs in one minute by voluntary effort. There are several factors on which the aforementioned lung volume and the airflow depend: **Compliance** (a volume term), which is a measure of the elastic properties of lung, is an important determinant. Other elements include **resistance** (a flow term) and **inertance** (an acceleration term).

Inertance

Since the respired gases, the lungs and the chest wall all have appreciable mass and therefore inertia, they offer an impedance to change in the direction of gas flow. This component called inertance is extremely difficult to measure, but offers impedance that increases with frequency. Hence, inertial pressure is essentially negligible for most clinical purposes and the gas flow depends primarily on the compliance and resistance characteristics of the lung parenchyma except in situations of increased respiratory frequencies like high-frequency ventilation.

Compliance

Pulmonary compliance (or distensibility) is defined as the change in the volume of the lung per unit change in the distending pressure, which in case of lung is the transpulmonary pressure [which is defined as the pressure gradient between the alveolar (P_A) and the pleural pressures (P_{pl})]. **Elastance** is the reciprocal of compliance. Compliance is equal to the exhaled tidal volume (or a change in lung volume) divided by the alveolar pressure minus the pleural pressure (or a change in the transpulmonary pressure).

$$C = \Delta V_L / \Delta (P_A - P_{pl}),$$

where C = lung compliance, ΔV_L = change in lung volume, $\Delta (P_A - P_{pl})$ = change in transpulmonary pressure.

The interaction between the recoil of the lungs and recoil of the chest can be demonstrated using body plethysmography. The technique is described in detail in the chapter on pulmonary function testing.

The lung pressure volume relationship is a curvilinear graph. The elastic recoil pressure of lung always tends to collapse the lung even at the residual volume. Theoretically therefore, if removed from the thoracic cage, the lungs collapse to almost an airless state. The pressure-volume curve is also slightly greater when measured during deflation than when measured during inflation, a property called hysteresis (Fig. 6.2). Hysteresis is affected by the elasticity of lung parenchyma (in fact, hysteresis is a universal property of all elastic materials) and the surface tension of alveolar spaces. Pulmonary compliance is normally measured in the pressure range where the relaxation pressure curve is steepest. However, compliance depends on lung volume with highest compliance at residual lung volume and low compliance at high lung volumes.

Recruitment

This is a unique phenomenon observed in lung due to the closure of some small airways at lower lung volumes. As the transpulmonary pressure rises, the closed airways open sequentially. Thus, the recruitment of additional lung units in the initial phase of inspiration starting from lower lung volumes also contributes to hysteresis. Two other important factors affecting lung compliance are the surface tension and the physical nature of lung tissues.

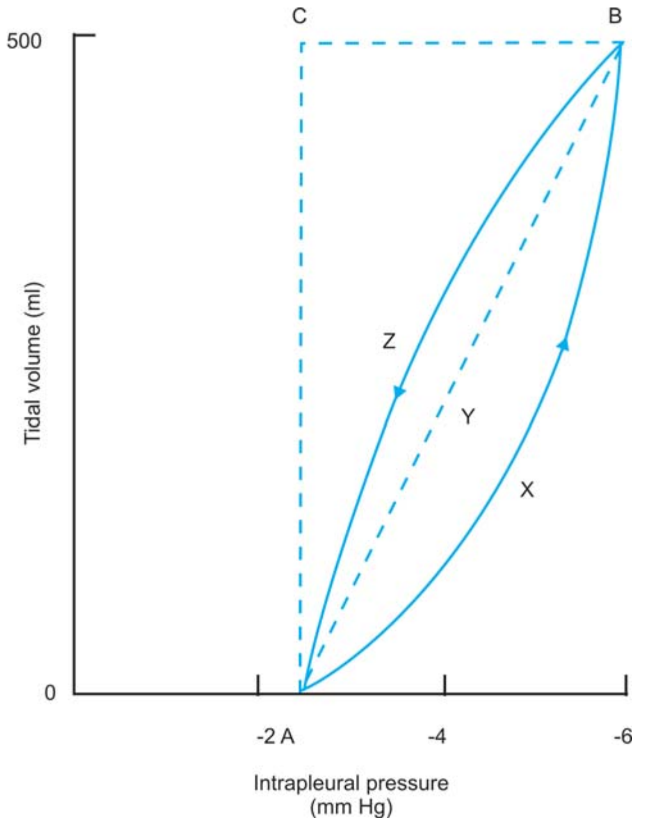

Fig. 6.2: Diagrammatic representation of pressure and volume changes during quiet inspiration (line AXB) and expiration (line BZA) is the compliance line

Surface tension exerted by the air fluid interface is reduced by surfactant—a surface active compound of phospholipids produced by type II alveolar cells. Surface tension is further lowered at lower lung volumes thereby increasing the compliance and decreasing the force required during the next inflation. Also by the Laplace law (Pressure = 2 × surface tension/radius), as the diameter of the alveoli is decreased, the pressure would increase and this would create an unstable system; this is also prevented by the surfactant, which decreases surface tension with decreasing radii of the alveoli, and allows gas to flow from the larger to the smaller alveolus and stability is maintained. This phenomenon is also mandatory for the maintenance of stability of alveoli at lower lung volumes.

Physical elastic properties of lung tissue per se, are due to the presence of elastic fibers in the pulmonary interstitium. Expansion in lungs is probably more due to unfolding and geometric rearrangement of elastic fibers rather than the actual lengthening. Ageing alters the elastin and collagen fibers in lungs and thus increases the compliance. Compliance is also increased in emphysema due to the loss of elastic fibers of alveolar walls. It is reduced wherever there is the stiffness and thickening of alveolar septae by processes such as fibrosis.

Elastic Properties of Chest Wall and Lung-Chest Wall Interactions

The resting volume of the thoracic cage is approximately equal to 70% of TLC. It implies that if thoracic cage is opened and support of lung withdrawn, it expands from FRC (the resting position of the respiratory system at which the inward elastic recoil of the lungs is exactly balanced by the outward recoil of the thoracic cage) to a volume of about 70% of TLC. At volumes less than 70% (including FRC) the thoracic cage has a tendency to expand and elastic recoil pressure is opposite to that of lungs, and is directed outwards.

The total compliance of the respiratory system is analogous to the electrical capacitance with the compliances of the lung and the thoracic wall arranged in series. Thus, the reciprocal of total compliance is the sum of reciprocals of the individual compliances, i.e.

1/total compliance = 1/lung compliance +
1/chest wall compliance

Instead of compliance, we may consider its reciprocal, elastance and the relationship is much simpler:

Total respiratory system elastance =
lung elastance + chest wall elastance

Resistance

Resistance is the opposition to motion and in the respiratory system opposition to the flow of gas. In the lung, resistance to air flow is of two types: tissue and airway. The former, also known as elastic resistance (resistance from tissues or tissue resistance), occurs when no gas is flowing, and is due to elastic resistance of lung tissue and chest wall and the resistance imparted from surface forces at the alveolar gas/liquid interface. Approximately 80% of the pulmonary resistance is due to airway resistance or non-elastic resistance.

Resistance to airflow is computed by the simultaneous measurements of airflow, and the driving pressure that is required to achieve the flow, i.e.

Resistance = Driving pressure/Flow = P/V

Most non-elastic resistance is provided by frictional resistance to airflow and thoracic tissue deformation, with small contributions from the inertia of gas and tissue and compression of intrathoracic gas.

Airway Morphology

Airways are the tubular structures designed to carry air to the alveolocapillary membrane for gas exchange. The tracheobronchial tree consists of several branches, which arise by dichotomous divisions of the parent bronchus. The airway divisions from trachea to the alveoli are not uniform and may vary between 10 and 25 in different areas—divisions being less near the hilar regions and more at the bases. The diameter, angulation and course of the bronchial divisions are also different in different lung zones. For example, the air passages to alveoli at the lung bases are straighter and have large cross-sectional areas. This asymmetric pattern of branching is referred to as "irregular dichotomy". It has a bearing on the distribution of ventilation and deposition of inhaled material.

Airways are classified into two types—conducting and respiratory airways. The conducting or central airways do not participate in gas exchange. They are larger than 2 mm in diameter, have cartilaginous support, are lined by ciliated columnar epithelium and are supplied by systemic bronchial circulation. They are also able to change their diameter in response to several neurohormonal and chemical stimuli due to the presence of smooth muscles in their walls and vagal innervation. The respiratory bronchioles or terminal airways are situated beyond the conducting airways. They are less than 2 mm in diameter, lack cartilaginous support, are lined by cuboidal epithelium and are supplied by pulmonary circulation. Due to their structural properties, they are susceptible to compression and closure in response to changes in the intrapulmonary pressures.

The geometric features of airway divisions have a direct relationship with the partitioning of resistance and hence distribution of ventilation. There is a progressive narrowing and shortening of airways as the division progresses from trachea to the peripheral airways. Despite the reduction in the diameter of daughter airways, the total cross-sectional area increases tremendously as we go peripherally. This is because the total number of airways increases geometrically with each division and the diameter of each daughter airway is more than half of the parent airway. This results in almost 2,000 fold increase in total cross-sectional area from trachea to peripheral airways.

Physical Principle of Gas Flow and Resistance

The geometric features described above are important in the distribution of resistance within the lung. Since flow is inversely proportional to the diameter of the tube, it decreases progressively as air moves down the bronchial tree to the peripheral zones. In the terminal bronchioles, flow is reduced to almost zero. It is the Brownian motion of the molecules, which facilitates diffusion across the alveolocapillary membrane. As the flow velocity decreases, the driving pressure and resistance also fall. It has been calculated that 80% of total measurable resistance at mouth is contributed by the central or conducting airways.

The precise relationship between pressure difference and flow rate depends on the nature of the flow, which may be laminar, turbulent or a mixture of the two. With laminar flow, gas flows along a straight unbranched tube as a series of concentric cylinders that slide over one another, with the peripheral cylinder stationary and the central cylinder moving fastest, the advancing cone forming a parabola. The advancing cone front means that some gas will reach the end of the tube despite the volume of gas entering the tube being less than the volume of the tube. This has relevance in patients being ventilated using the high frequency ventilation where there is significant alveolar ventilation despite the tidal volume being less than or equal to the anatomical dead space.

In a straight unbranched tube, the Hagen-Poiseuille equation allows gas flow to be quantified:

$$\text{Flow rate} = \Delta P \times \pi \times (\text{radius})^4 / 8 \times \text{length} \times \text{viscosity, where}$$

ΔP is the pressure gradient and equals the product of flow rate and resistance:

Thus, resistance = $8 \times \text{length} \times \text{viscosity} / \pi \times (\text{radius})^4$

In this equation, the fourth power of the radius explains the critical importance of narrowing of the air passages. With constant tube dimensions, viscosity is the only property of gas that is relevant under the conditions of laminar flow. Helium has a lower density, but a viscosity close to that of air, and thus will not improve gas flow if the flow is laminar.

On the other hand, turbulent flow occurs when gas flows at high rates through unbranched or irregular tubes, resulting in the formation of eddy currents. In contrast to laminar flow, it has a square front and the volume of gas entering the tube is equal to the volume of the tube, the so called bulk flow. The relationship is different from the laminar flow in that the driving pressure is proportional to the square of the gas flow rate and the density of gas, but independent of its viscosity and the required driving pressure is inversely proportional to the fifth power of the radius of the tubing (Fanning's equation).

The change in flow from laminar to turbulent characteristics is determined by a dimensionless number, the

Reynolds' number (N_R), which is N_R = density × velocity × diameter/viscosity. The property of gas that affects N_R is the ratio of density to viscosity. Flow is laminar with N_R less than 2,000, and changes from laminar to turbulent when the N_R exceeds 4,000. Between N_R of 2,000 and 4,000, both types of flow coexist. There is also a critical length of tubing before the parabolic pattern of laminar flow is established, and thus for gases with low N_R not only will resistance be less during turbulent flow, but also laminar flow will become established more quickly after narrowed airways. In principle, turbulence occurs only in the larger airways and not in the smaller airways because of the large cross-sectional area, the small diameter and the slow velocity of the small airways. Heliox has a density/viscosity ratio of 0.31 compared to one for oxygen. If thus has a lower N_R and higher potential for laminar flow, explaining its usefulness in patients with large airway diseases.

Total and Alveolar Ventilation

The total amount of air inhaled with each inspiration gets distributed in the lungs depending upon the regional resistance and compliance of the different lung units. Ventilatory requirements for adequate supply of oxygen and removal of carbon dioxide depend on the metabolic demands of the body. The resting ventilatory requirements are small and are met with minimal expenditure of energy. A normal individual can maintain gas exchange with a ventilation of about 80 ml/kg/minute, which is about one-tenth of the maximum ventilatory capacity. Therefore, there is a vast reserve in ventilatory capacity and problems of gas exchange would not occur, if all the inspired volume is available to the gas exchange units. However due to cyclical nature of ventilation, a significant proportion of the inspired gas never reaches the alveoli—a volume known as the dead space volume. So, the total ventilation is contributed by the dead space ventilation (V_D) and alveolar ventilation (V_A), i.e. the air that reaches the alveoli to take part in gas exchange. The dead space ventilation in mL is roughly around the individual's body weight in pounds.

The volume of conducting airways, which constitute the anatomical dead space is relatively fixed, i.e. about one-third of the tidal resting ventilation. Its relative proportion to the total ventilation decreases as the total ventilation increases, for example on exercise. On the other hand, a decrease in tidal volume and increase in respiratory rate (e.g. rapid shallow breathing) markedly increases the proportion of dead space ventilation thereby affecting the gas exchange.

Dead space is also increased when there is presence of lung units, which are adequately perfused, but not ventilated, the so called physiological dead space. It is important to distinguish between the anatomic dead space (respiratory system volume exclusive of alveoli) and the physiologic dead space (volume of gas in the alveoli not equilibrating with blood, i.e. wasted ventilation). As will be discussed subsequently in this chapter, ventilation has to be matched by the perfusion of blood in the alveolar capillaries for adequate gas exchange to occur. Ventilation and perfusion are not homogeneously distributed throughout the lung, and areas which receive more ventilation relative to perfusion result in wasted ventilation and thus add to "dead space" ventilation. The sum of the dead space ventilation by these two mechanisms constitutes "total dead space" and is given the formula:

V_D/V_E = $1 - P_ECO_2/P_ACO_2$, where
V_D = total dead space
V_E = minute ventilation
P_ECO_2 = partial pressure of carbon dioxide in the expired air
P_ACO_2 = partial pressure of carbon dioxide in the alveolar air (which in practice is measured by the arterial PCO_2)

The relationship of total and alveolar ventilation was first described by Christian Bohr and is also known as "Bohr dead space".

Distribution of Ventilation

The alveolar ventilation is distributed throughout the lungs. With each inspiration around 500 ml of air is distributed to around 300 million alveoli such that each alveolus receives an appropriate share of the inspired gas. This fine distribution of air is essentially a function of the "time constants" of the regional lung units. Time constant is the product of regional compliance and resistance and thus is also called the RC time constant. The relative distribution of ventilation between two neighboring lung units can be understood better with the two compartment lung model. In health, the resistance and compliance of two adjacent units of lung are essentially equal and thus their RC time constant is normal with the normal distribution of ventilation. However in a diseased lung, different portions of the lung may have abnormal time constants as a result of either the diseased airway lumen (increased resistance) or because of stiffness of alveolar walls (increased compliance) or both. Thus, ventilation will be maldistributed in a lung unit with abnormal RC time constant with more ventilation to areas with relatively normal time constant than other areas. A lung unit with a large time constant (i.e. greater resistance and compliance) does not completely fill by the end of inspiration and empties slowly during expiration. In contrast, a lung unit with a small time constant (i.e. smaller resistance and compliance) fills and empties rapidly.

When a lung unit with a large time constant is located adjacent to a lung unit with a small time constant, the unit with the large-time constant may withdraw gas from the adjacent lung unit with a short-time constant rather than fresh inspired gas. This "to and fro" behavior is known as pendelluft, and it can occur in abnormal lungs. In addition, a lung unit with a small time constant may receive a higher proportion of dead space gas, which reduces its alveolar ventilation. This effect is prominent in chronic obstructive lung disease, in which compliant lung units with extremely large time constants behave essentially as dead space. The higher the respiratory rate, the greater is the discrepancy in filling and emptying between these two kinds of units, and thus greater the inhomogeneity of ventilation.

Another reason for uneven ventilation of small lung units is a gradient of gas concentration along the small airways, a condition called stratified inhomogeneity. Inspired gas reaches near the region of the terminal or respiratory bronchioles by convective flow, but gas flow over the rest of the distance to the alveoli is accomplished primarily by molecular diffusion within the airways. When airway calibers are altered, as in emphysema, the process of gas diffusion may be incomplete for each breath. Thus, alveoli more distal to the conducting airways are less well ventilated than proximal alveoli.

Several mechanisms tend to preserve the uniform distribution of ventilation in the lung. One of these mechanisms is the pendelluft phenomenon described above. Another mechanism is gas exchange through collateral air channels between adjacent lung units. Collateral ventilation can occur between alveolo-alveolar pores of Kohn, bronchioloalveolar canals of Lambert, and bronchiolobronchiolar foramina of Martin. Another factor that tends to improve the uniformity of ventilation is the interdependence of peripheral lung units, which stems from the observation that contiguous lung units are attached integrally to each other by the connective tissue framework of the lung parenchyma. The behavior of one unit must therefore influence the behavior of its neighbors. This framework serves to offset the tendency for regional differences in compliance to make lung units larger or smaller than they should be for optimal performance.

Role of Gravity

Gravity also plays some role in the distribution of ventilation. In the upright position, ventilation per unit lung volume is greater at the base of the lung than at the apex. The reason for this is that at the start of inspiration, intrapleural pressure is less negative at the base than at the apex, and since the intrapulmonary-intrapleural pressure difference is less than at the apex, the lung is less expanded. Conversely, at the apex, the lung is more expanded; i.e. the percentage of maximum lung volume is greater. Because of the stiffness of the lung, the increase in lung volume per unit increase in pressure is smaller when the lung is initially more expanded, and ventilation is consequently greater at the base.

The ventilation differences tend to disappear in the supine position, and the weight of the lung makes the intrapleural pressure lower at the base in the upright position. However, the inequalities of ventilation and blood flow in humans have been found to persist to a remarkable degree in the weightlessness of space. Therefore, other as yet unknown factors apparently also play a role in producing the inequalities. It should also be noted that at very low lung volumes, such as those after forced expiration, intrapleural pressure at the lung bases can actually exceed the atmospheric pressure in the airways, and the small airways such as respiratory bronchioles collapse (airway closure). In older people and in those with chronic lung disease, some of the elastic recoil is lost, with a resulting decrease in intrapleural pressure. Consequently, airway closure may occur in the bases of the lungs in the upright position without forced expiration, at volumes as high as the functional residual capacity.

PULMONARY CIRCULATION

The circulation of the entire cardiac output through the lungs is ideally suited for rapid gas exchange. The pulmonary vascular bed resembles the systemic circulation, except that the walls of the pulmonary artery and its large branches are about 30% as thick as the wall of the aorta, and the small arterioles, unlike the systemic arterioles, have relatively little muscle in their walls. There is also some smooth muscle in the walls of the postcapillary venules. Also, the pulmonary capillaries are large with multiple anastomoses, so that each alveolus sits in a capillary basket. The blood from the right side of the heart flows through an intricate network of pulmonary capillaries around the alveoli.

After getting oxygenated, blood drains back into the left atrium through four pulmonary veins. The pulmonary bed is characteristically a low-pressure circuit. There is a dense network of capillaries around each alveolus. Rough estimates put the total number of capillaries at about six billion or two thousand capillaries per alveolus. Not all the capillaries are perfused under resting conditions. An increased blood flow due to an increased cardiac output (as much as 25 liters per minute during exercise in contrast to five to six liters during resting conditions) can be accommodated easily in the pulmonary circulation without an increase in the pulmonary arterial pressure. This is made possible as a result of two major mechanisms that include recruitment, which is the opening of previously unperfused pulmonary capillaries in the upper lung zones, and distension in the entire pulmonary vasculature due to increased transmural pressure gradient. The best example of the ability of pulmonary vasculature to adapt to increased blood flow is following pneumonectomy, when the remaining lung will normally take the entire resting pulmonary blood flow without an increase in pulmonary arterial pressure.

Distribution of Perfusion

The distribution of pulmonary blood flow is non-uniform from apex to base. In the upright position, the upper portions of the lungs are well above the level of the heart, and the bases are at or below it. Consequently, there is a relatively marked pressure gradient in the pulmonary arteries from the top to the bottom of the lungs, because of the effect of gravity, and a resulting linear increase in pulmonary blood flow from the apices to the bases of the lungs. The following three concepts about pressure in the pulmonary vessels are important to understanding the behavior of the pulmonary circulation.

Intravascular Pressure

This is the blood pressure inside the lumen of the vessel relative to the atmospheric pressure. The pulmonary arterial pressure (P_a) and pulmonary venous pressure (P_v), can be measured directly by placing catheters into the bloodstream at specific points, and in clinical practice, capillary pressure can be estimated by wedging a catheter into a lobar branch of pulmonary artery. The “wedge” pressure measured under the conditions of “no flow” reflects the pressure downstream of the next freely communicating channels, that is, pulmonary capillaries or small pulmonary venules.

Transmural Pressure

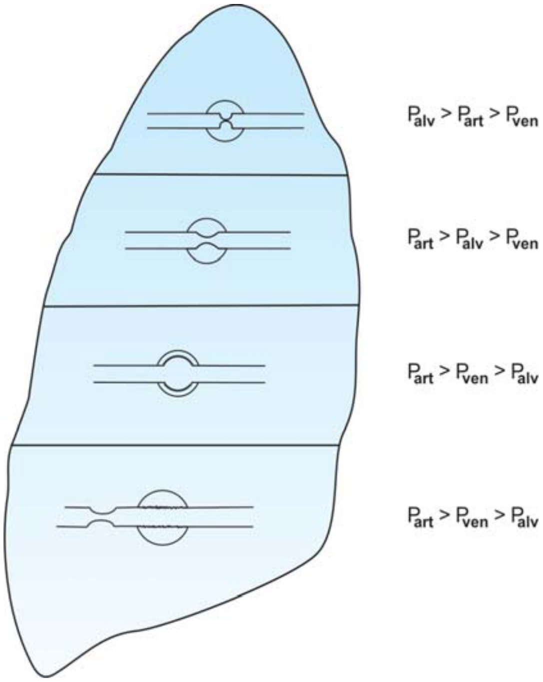
This is the difference between the pressure inside a vessel and the pressure in the tissue around it. For example, the pressure around the pulmonary arteries and veins is approximately equal to the intrapleural pressure. The pressure around the capillaries is approximately the intra-alveolar pressure (P_A). It is this difference in transmural pressure that leads to the different behavior of alveolar and extra-alveolar vessels under conditions such as lung inflation. At the capillary level, the transmural pressure is also an important determinant of the rate of transudation of fluid across the capillary bed.

Pulmonary Driving Pressure

This is the difference in intravascular pressure between one point in the circulation and another point downstream, and is the pressure involved in overcoming the frictional resistance that impedes blood flow between two points. The driving pressure for the pulmonary circulation is the difference between the intravascular pressure in the main pulmonary artery and that immediately after the pulmonary circulation in the left atrium.

The intravascular pressures of the pulmonary circulation are influenced by the hydrostatic pressure created by gravity and the alveolar pressures significantly affect the intra-alveolar capillaries. As alveolar pressure is relatively independent of gravity, the relationships among pulmonary arterial, pulmonary venous and alveolar pressures must also influence the distribution of pulmonary blood flow. West subdivided the lung into four zones with differing patterns of blood flow (Fig. 6.3). In ***zone 1***, near the apex of the lung, wherein the alveolar pressure exceeds both the pulmonary arterial and venous pressures ($P_A > P_a > P_v$), and thus the alveolar vessels are collapsed and there is no pulmonary blood flow. In ***zone 2***, the pulmonary arterial pressure exceeds the alveolar pressure, but alveolar pressure exceeds venous pressures ($P_a > P_A > P_v$). Under these conditions, the resistance to blood flow is determined by the difference between pulmonary arterial and alveolar pressures, rather than by the expected arterial-venous pressure difference. This behavior has been referred to variously as the waterfall or sluice effect. Also in ***zone 2***, blood flow increases progressively down the lung because of the increasing hydrostatic effect on pulmonary arterial pressure, which increases the driving pressure in this region (pulmonary arterial pressure minus alveolar pressure).

In ***zone 3***, the pulmonary venous pressure exceeds alveolar pressures ($P_a > P_v > P_A$), and blood flow is dependent on the pressure difference between P_a and P_v, and is maximal. There is also a progressive increase in the perfusion because of the progressive “distension” of vessels due to increase in P_a and P_v, while P_A remains



$P_{alv} > P_{art} > P_{ven}$
$P_{art} > P_{alv} > P_{ven}$
$P_{art} > P_{ven} > P_{alv}$
$P_{art} > P_{ven} > P_{alv}$

Fig. 6.3: West zones of perfusion

constant. In ***zone 4***, the relationships between intravascular and alveolar pressures are the same as in zone 3, but the blood flow decreases slightly. Zone 4 occurs in the lowermost region of the upright human lung and diminishes as lung volume increases. Conversely, as lung volume decreases, this region of reduced blood flow extends farther and farther up the lung, so that at FRC blood flow decreases progressively down the bottom half of the lung. At residual volume, zone 4 extends nearly all the way up the lung, so that blood flow at the apex exceeds that at the base. This condition obviously cannot be explained by the interactions among the pulmonary arterial, venous and alveolar pressures. Instead, the reduced blood flow in zone 4 is probably due to the narrowing of extra-alveolar vessels at the lung base that result from lower lung inflation due to airways closing down at the "closing volume". The increased contribution of extra-alveolar vessels to pulmonary vascular resistance results in the presence of a zone of reduced blood flow in that region. Zone 4 would be expected to increase in the presence of interstitial pulmonary edema, because the edematous fluid increases interstitial pressure in the vascular sheath and thereby narrows the extra-alveolar vessels. This is a plausible mechanism for the inverted distribution of blood flow (cephalization of pulmonary vasculature on chest X-ray) in pulmonary edema.

However, not all the inhomogeneity of blood flow in the lung can be explained by gravitational effects. Indirect measurements of inhomogeneity (monitoring the magnitude of cardiogenic oscillations on the expired carbon dioxide tracing) of pulmonary blood flow have been made in astronauts in space shuttles, and a striking reduction in inhomogeneity of blood flow was detected during weightlessness compared with that observed in the upright posture before or after the flight. Interestingly, substantial inhomogeneity of blood flow still remained, indicating that some gravity-independent mechanism was also present. Another situation where the gravitational model fails is the situation of prone position ventilation, where the perfusion is probably more homogeneous and not dependent on gravity.

DIFFUSION

Diffusion is the rate at which oxygen from the alveolus is transferred across the alveolocapillary barrier to combine with hemoglobin in the red blood cells of pulmonary capillaries (Fig. 6.4). The situation in lungs can be visualized as a two chamber model with different partial pressures of oxygen and a liquid barrier separating the two (Fig. 6.4). The transfer of gases from

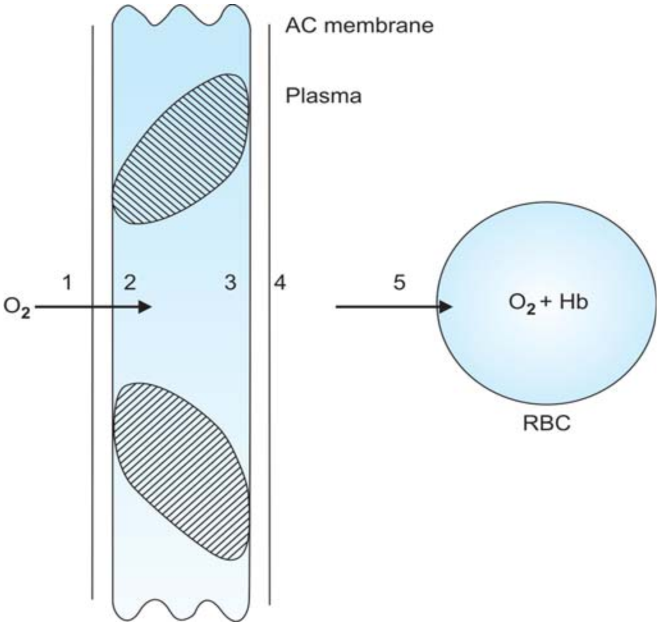


Fig. 6.4: Schematic diagram representing diffusion across the alveolocapillary membrane into the red blood cell. 1 and 2 represent the inner and outer layer of the alveolar epithelium, 3 and 4 represent the inner and outer layer of the capillary endothelium, 5 represents the red blood cell membrane

the alveoli to the capillary blood during the pulmonary transit time of 0.75 seconds depends on their reaction of the molecules with hemoglobin in the blood. For example, nitrous oxide (N_2O) does not react, and reaches equilibrium in about 0.1 seconds. In this situation, the amount of N_2O taken up is not limited by diffusion, but by the amount of blood flowing through the pulmonary capillaries; i.e. it is flow-limited.

On the other hand, carbon monoxide (CO) is taken up by the hemoglobin in the red blood cells at such a high rate that the partial pressure of CO in the capillaries stays very low and equilibrium is not reached in 0.75 seconds till the blood is in the pulmonary capillaries. Therefore, the transfer of CO is not limited by perfusion at rest and instead is diffusion-limited. Oxygen is intermediate between N_2O and CO; it is taken up by hemoglobin, but much less avidly than CO, and it reaches equilibrium with capillary blood in about 0.3 seconds. Thus, its uptake is also perfusion-limited. The diffusing capacity of the lung for a given gas is directly proportionate to the surface area of the alveolocapillary membrane and inversely proportionate to its thickness. The factors that influence the movement of gas from the area of higher partial pressure (alveolus) to the area of low partial pressure (capillaries) are governed by the Fick's law:

V = Ad/T (P1 - P2), where
V = volume of gas diffusing per unit time (ml/minute)
A = area available for diffusion (cm^2)
P1 - P2 = pressure difference of gas on two sides (mm Hg)
d = diffusion coefficient of the barrier (cm^2/minute/mm Hg)

This **diffusion coefficient** "d" is further related to the solubility of the gas within the liquid barrier and the square root of the molecular weight of the gas. Other factors being constant, the driving pressure is the most important factor determining the flow of oxygen across the alveolocapillary membrane. When this pressure falls, such as travel at high altitudes, the oxygen delivery to the tissues becomes diffusion limited. Similarly, diffusion is inversely proportional to the thickness of the membrane.

Although diffusion is reduced in the presence of thickened alveolocapillary membrane (e.g. interstitial lung disease) or the loss of gas exchange areas (e.g. chronic obstructive airway disease); however, it is rarely the sole factor responsible for hypoxemia encountered in these conditions. The reason is that the transfer of oxygen and carbon dioxide is perfusion limited. The normal capillary transit time across the alveolar walls is usually 0.75 seconds, but in healthy individuals only 0.25 seconds is required for gas exchange to be completed. Thus, there is an adequate time for gas exchange to occur even in the presence of a diffusion defect. The gas exchange however becomes diffusion dependent during conditions, which increase cardiac output, such as exercise, anxiety, etc. when the capillary transit time is significantly reduced.

VENTILATION-PERFUSION (V/Q) RELATIONSHIPS

The ratio of pulmonary ventilation to pulmonary blood flow for the whole lung at rest is about 0.8 to 1 (4-6 liters/minute ventilation divided by 5–6 L/minute blood flow), and this matching of distribution of ventilation and perfusion is the most important determinant of gas exchange. The ventilation-perfusion mismatch is the final common pathway to cause hypoxemia in most pulmonary diseases (Fig. 6.5). An area of lung that is well perfused, but under ventilated acts as a right to left shunt (physiological shunt) whereas an area that is well ventilated, but under perfused acts like a dead space (physiological dead space). The spectrum of $\dot{V}/\dot{Q}$ ratios in a healthy lung would vary between zero (perfused, but not ventilated) to infinity (ventilated, but not perfused).

The ideal $\dot{V}/\dot{Q}$ratio of one indicates perfectly matched ventilation and perfusion. Although $\dot{V}/\dot{Q}$ mismatch includes both physiologic shunt and physiologic dead space, but in clinical parlance, the term generally denotes physiologic shunt as physiologic dead space, is rarely, if ever the cause of hypoxemia. In an alveolar-capillary unit with a $\dot{V}/\dot{Q}$ ratio of 0 (physiologic shunt), the blood

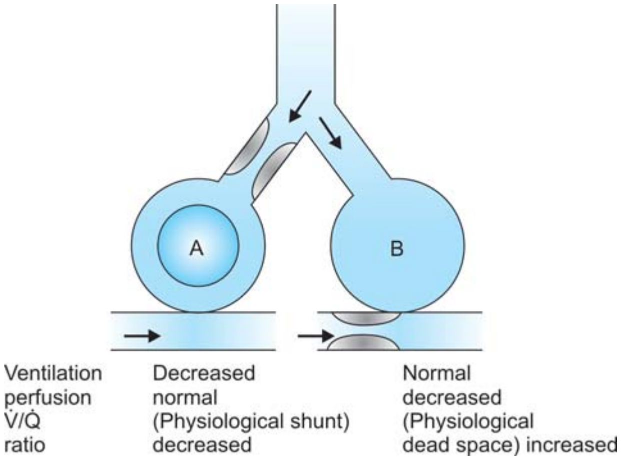

Fig. 6.5: Mismatching of ventilation and perfusion: Model A (diminished ventilation) and B (decreased perfusion)

leaving the unit has the composition of mixed venous blood entering the pulmonary capillaries, i.e. PO_2 of 40 mm Hg and PCO_2 of 46 mm Hg whereas in an alveolar-capillary unit with a high $\dot{V}/\dot{Q}$ ratio (physiologic dead space) the small amount of blood leaving the unit has partial pressures of O_2 and CO_2 are 150 mm Hg and 0 mm Hg approaching the composition of inspired gas.

Because of the sigmoid shape of the oxyhemoglobin dissociation curve, it is important to differentiate between the partial pressure and the content of oxygen in the blood. Hemoglobin is almost fully (> 90%) saturated at a PO_2 of 60 mm Hg, and little additional O_2 is carried by hemoglobin even with a substantial elevation of PO_2 above 60 mm Hg. On the other hand, significant O_2 desaturation of hemoglobin occurs once PO_2 falls below 60 mm Hg and onto the steep descending limb of the curve. As a result, blood coming from regions of the lung with a high $\dot{V}/\dot{Q}$ ratio and a high PO_2 has only a small elevation in O_2 content and cannot compensate for blood coming from regions with a low $\dot{V}/\dot{Q}$ ratio and a low PO_2, which has a significantly decreased O_2 content. Although $\dot{V}/\dot{Q}$ mismatching can influence PCO_2, this effect is less marked and is often overcome by an increase in overall minute ventilation.

The alveolar PO_2 appears to be the most important factor involved in regulating the distribution of ventilation-perfusion within the lung. In this respect, hypoxic pulmonary vasoconstriction can be considered as part of a negative feedback loop. For example, in lung units with low $\dot{V}/\dot{Q}$ ratios, there is a fall in the local alveolar PO_2, and constriction of the associated microcirculation reduces the local pulmonary blood flow. This tends to restore the loca $\dot{V}/\dot{Q}$ ratio toward its normal value. This effect can be appreciated in the residents of high altitudes, who are exposed constantly to lower ambient O_2 concentrations. Residents of high altitudes have better $\dot{V}/\dot{Q}$ matching than sea level residents, as reflected by a smaller alveolar-arterial PO_2 difference. The intensity of hypoxic pulmonary vasoconstriction varies among different lung regions, and probably depends on the smooth muscle tone in different vessels. More recently, a role for nitric oxide in regulating local ventilation-perfusion matching has been suggested as nitric oxide is a selective pulmonary vasodilator (no systemic effects), and inhibits hypoxic pulmonary vasoconstriction. Theoretically, the inhalation of nitric oxide can cause selective pulmonary vasodilation in adequately ventilated areas and improve gas exchange. The nitric oxide-mediated mechanism may also be important in patients with inflammatory lung diseases, in whom the production of nitric oxide is increased. The loss of local hypoxic vasoconstriction would worsen ventilation-perfusion mismatch.

CONTROL OF VENTILATION

The active inspiratory process facilitates expansion of the lungs. It involves the contraction of intercostals muscles and diaphragm to move the chest upwards and outwards. By doing so the intrathoracic and alveolar pressures are lowered and the flow of the air into the lungs is facilitated. Expiration is usually a passive process. The lungs and chest collapse under their own elastic recoil and raise the intrathoracic and alveolar pressures. The air flows out of the lungs.

Ventilation is controlled tightly through three components—sensors (or receptors), central controllers and effectors (muscles of respiration). The respiratory control mechanisms operate through both neuronal and chemical receptors. While the former are peripherally located (airway, lung, chest wall, blood vessels), the latter are both peripherally and centrally located. Control centers in the brain put together information from all these receptors, and fine-tune the neuronal drive to respiratory musculature, which in turn controls the level of ventilation.

Neuronal Receptors

The neuronal receptors vary greatly in their location and response characteristics. Some are rapidly adaptive to change in lung volume or irritation by noxious agents or inflammatory mediators. Receptor signals are mediated through the vagus nerve to the respiratory center, and have variable effects like increase in ventilation, cough and/or bronchoconstriction. Others like stretch receptors or muscle spindles in airway smooth muscles adapt slowly to lung volume changes. These get activated by lung overdistension and signal the respiratory center to discontinue the stimulation of the inspiratory muscles, allowing expiration to begin. This response is called the inflation (Hering-Breuer) reflex. Juxtacapillary (or J) receptors located in alveolar walls sense the engorgement of the pulmonary capillaries and cause rapid shallow breathing.

Peripheral Chemoreceptors

The main location for peripheral chemoreceptors is in the aortic and carotid bodies, although they may be present in other areas as well. Carotid bodies are located bilaterally at the bifurcation of common carotid arteries, and are the major receptors in adult life. They mainly respond to arterial hypoxemia, and also to hypercapnia, by transmitting signals to the nucleus tractus solitarius through the ninth cranial nerve, resulting in hyperventilation. Other chemoreceptors in the central nervous system adjust ventilation to maintain acid-base homeostasis. The more important receptors are located near the ventral medullary surface and the retrotrapezoid nucleus. These receptors respond to pH changes in the cerebrospinal fluid resulting from the diffusion of carbon dioxide through the blood-brain barrier.

Respiratory Center

The various positive and negative signals from all these receptors are integrated at the level of respiratory control centers in the medulla and pons, and result in appropriate modifications in frequency, depth and/or pattern of respiration. The dorsal medullary inspiratory center generates rhythmic neuronal impulses that result in the contraction of inspiratory muscles. Exhalation is largely a passive process, though it can be actively controlled through the ventral respiratory group of neurons in the medulla. The medullary center is controlled by pontine centers. The pneumotaxic center is located in the dorsal and superior pontine area, and is inhibitory to the medullary ventilatory drive. The apneustic area in the lower pons can stimulate respiration if the pneumotaxic center is blocked, but its function is not well understood.

Ventilatory Responses

The ventilatory response to carbon dioxide elevation in the blood is largely centrally mediated and results in a proportional increase in ventilation that attempts to correct the anomaly, although normocapnia may not be achieved. The relationship between respiratory minute volume and the alveolar carbon dioxide is essentially linear. The ventilatory response to hypoxia is not so linear. Although mild hypoxemia increases discharge from the peripheral chemoreceptors, the corresponding hypocapnia from any increase in ventilation, as well as a slight alkalosis from the lesser amount of oxyhemoglobin, prevent any sustained hyperventilation. An increase in minute ventilation is only seen when arterial oxygenation falls substantially. The composite effects of hypoxemia, hypercarbia and acidosis are much more complex.

Gas and Fluid Exchange in the Lung

Marc Zelter

GAS EXCHANGE

The oxygen needed by cell mitochondria for tissue respiration is extracted from atmospheric air by a succession of processes,[1] including external ventilation between the lung and the air, gas distribution and gas exchange in the lung, transport of oxygen by blood and transfer to the tissues (Fig. 7.1). Carbon dioxide, one of the two main by-products of tissue respiration, the other one being water, follows the reverse pathway. The flow process is possible because the partial pressure of oxygen decreases from one step to the next, creating the physical conditions necessary for the transfer of gas from the lung to the cell (Fig. 7.2). The series of steps or pressure changes in oxygen from one step to the next are not even. Each of the steps involved can be characterized by what is called its "conductance," defined as the maximum quantity of oxygen that can be transferred from one step to the next, per unit of time and per unit of oxygen pressure difference. The actual mechanisms by which oxygen follows these steps may vary from one step to the other: Forced convection between atmosphere and alveoli; passive diffusion across the alveolar wall and plasma; diffusion and reversible chemical bondage between plasma and intracellular red cells hemoglobin; forced convection from the lung to tissues via the systemic circulation; and passive diffusion from red cells to the tissue interstium and then by diffusion to tissue cells and mitochondria. The oxygen that has not been extracted by tissues follows the reverse pathway back to the lungs. Two of these steps require energy expenditure: ventilation and circulation.

Modified from Dejours[1]

Whatever the transport mechanisms, the system is built and regulated in such a way that the amount of oxygen used for metabolism by the cells in stable conditions is always equal to the amount extracted by the lung; the amount of carbon dioxide expired by the lungs per unit of time equals the amount produced by the cells. The two processes are called the “oxygen consumption” and “carbon dioxide production.” Both are independent of changes in ventilation as long as enough oxygen is made available to the tissues. For instance, hyperventilation as such has no influence on oxygen consumption or carbon dioxide production provided the tissue metabolism is not modified, although the amount of oxygen entering the lung per unit of time is higher than during normal ventilation. The amount of oxygen that enters the lung and is contained in the inspired air per unit time (the oxygen intake) is always larger than the amount transferred from the alveoli to the blood (the oxygen consumption). What is left is expired during the next breath. The same does not apply to carbon dioxide, as there is no carbon dioxide in the inspired air, so the amount expired per unit of time is that actually produced at tissue level, provided conditions have remained stable.

The same reasoning applies to both gases in the blood. The amount of oxygen present in the blood at the output of the lung is higher than what is needed by the tissues, but the tissues extract only what correspond to their consumption so that the quantity extracted from the blood by the tissues is equal to what has been extracted from the alveoli by the blood. What remains is brought back to the pulmonary artery, which is the lung input. The volume of carbon dioxide leaving the blood in the lung is equal to the carbon dioxide produced in the tissues, which is always less than what is transported by the pulmonary artery so that there is always carbon dioxide left in the oxygenated blood leaving the lung via the pulmonary veins. The design of the system is such that the amount of oxygen present at the output of the lung is almost always the maximum in a normal individual. The concentration of oxygen in the blood leaving the lung is, therefore, fixed and independent of oxygen consumption. It is called the arterial blood oxygen concentration (CaO_2), as it is the concentration of oxygen reaching the systemic arteries. The amount of oxygen actually present in the arterial blood is routinely evaluated by measuring the partial pressure of oxygen (PaO_2) rather than the concentration; this pressure is a precious index of the ability of the lung to saturate the blood in oxygen. It is also a good index that blood can carry enough oxygen to the tissues presuming that hemoglobin concentration in the blood and blood flow are adequate.

Inspired Gas

Inspired gas is best described in terms of pressure and composition. Gas is inspired at barometric pressure P_B. At sea level, pressure is about 760 mm Hg (100 kPa); it diminishes with altitude and rises during diving or during hyperbaric treatment. Inspired gas contains essentially atmospheric air, a defined chemical mixture of oxygen (21%) and nitrogen (79%) with no carbon dioxide, plus a variable amount of water vapor. Atmospheric air composition does not change with barometric pressure. Its composition remains the same at altitude and at sea level. What varies is the pressure at which it is inhaled. Composition of air may be expressed in terms of fractions of gas mixture: the fraction (F) is the percentage of one of the components in the mixture (F_IO_2 = 0.21 for oxygen, in inspired air). It may be expressed as partial pressure. Partial pressure is the fraction of total pressure due to each component of the gas mixture: P_{O_2}= 0.21× P_B = 160 mm Hg for dry air. Pressure of water vapor in the atmosphere varies with meteorological conditions. Inspired atmospheric gas is immediately heated up to body temperature (37° C) and saturated with water vapor in the trachea. Therefore, the actual inhaled gas mixture consists of dry air and water vapor. Physical laws determine the maximum amount of water vapor that can mix with air at 37° C without condensation; it depends only on temperature. The saturated water partial pressure at body temperature is 47 mm Hg. Barometric pressure being unchanged, the saturated partial pressure of water vapor being 47 mm Hg, the partial pressure of air in the inhaled mixture is P_B-47 = 713 mm Hg and consequently P_IO_2= 0.21 × 713= 150 mm Hg.

Expired Gas

After loosing oxygen to, and gaining carbon dioxide from the blood, the gas is expired from the alveoli. Because each molecule of oxygen consumed is not necessarily replaced by one molecule of carbon dioxide produced, the number of molecules expired per unit time and Volume may vary with the $\dot{V}CO_2$ /   ratio, called the respiratory quotient (R). This quotient is a function of the nutriments burnt by the tissues. R = 1, 0.7 or 0.8 respectively when the diet consists only of carbohydrates, lipids or proteins. The average value is 0.84 for a standard diet. Therefore, for each mole of oxygen consumed, only 0.84 mole of carbon dioxide is produced so that fewer molecules are present in the expired gas compared to the inspired gas. This represents a change of fraction of 0.03 and is generally neglected unless focus is on metabolic exchange or oxygen consumption. Therefore, although expired gas flow ($\dot{V}_E$) is lower than inspired gas flow ($\dot{V}_I$), they are considered equal in routine measurements.

The composition of expired gas depends also on the composition of inspired gas, normally dry air and water vapor. It may change if the subject is given oxygen therapy, or with metabolic activity(   ), with R if diet changes, and on ventilation. Ventilation (   ) is the flow produced by the action of the respiratory muscles on the thoracic cage and, therefore, on the lung. The flow is the product of the volume of each inspiration, also called the tidal volume (V_T), multiplied by the number of expirations per unit of time, the ventilatory frequency (f.   = V_T × f).

DEAD SPACE AND ALVEOLAR GAS

Gas exchange between inspired gas and blood occurs at the alveolar level, so gas has to be transported from the mouth to the alveoli by conducting airways. Conducting $\dot{V}O_2$ airways do not participate in gas exchange. They are part of what is called the "Dead Space" (V_D), around 150 ml. Functionally, the lung is therefore separated by a compartment, the dead space, which does not participate in gas exchange, but drives gas to where exchange occurs, and a compartment that participates in gas exchange called the Alveolar Volume (V_A).   and   are disposed in series. These definitions are physiological and do not strictly correspond to any precise anatomical volumes: Indeed the conducting airways are part of V_D but that is also true of part of the anatomical alveolar volume, because only a fraction of the anatomical alveoli participate in gas exchange at a given time. Consequently, V_A is always smaller than the anatomical alveolar volume.

The fraction of inspired gas flow that truly contributes to gas exchange is the flow that ventilates the functional part of the alveolar volume, called Alveolar Ventilation (   ). It is the useful part of   . The Inspired Flow (   ) is the sum of   and   . The end result is that during each cycle of 450 ml of tidal volume, 150 ml serve to ventilate dead space and only 300 ml participate in the exchange process. The composition of inspired gas does not change during inspiration and the composition of expired gas varies in time during expiration. First, the volume of gas contained in the dead space is expired.

TABLE 7.1: Normal values of pressures in inspired, expired, alveolar gas and in blood (mm Hg)

	I	*E*	*A*	*a*	$\bar{v}$
P_{CO_2}	0	26	39	39	44
P_{O_2}	150	118	102	91	38
P_{N_2}	563	569	572	572	572
P_{H_2O}	47	47	47	47	47
P_{total}	760	760	760	749	701

a: arterial blood, $\bar{v}$: mixed venous blood

It is the gas that was inspired at the end of the previous inspiration and because it had remained in the dead space, it did not participate in gas exchange. Its composition is that of inspired gas. Then, a mixture of inspired gas and alveolar gas and finally pure alveolar gas are successively expired. Alveolar gas composition can be reasonably approximated in a normal subject by sampling either the end tidal gas (gas at the end of a normal expiration) or better yet, the end forced expiratory gas.

The normal values for inspired, expired and alveolar gas are given in Table 7.1.

Ventilation equations can be computed from what is called the monocompartment alveolar model. The model consists of a fully functional monoalveolar lung and a single dead space.[2]

The equations are:

$$= [(0.863 \times \qquad [1–F_IO_2\ (1–R)]]/(P_IO_2\text{-}P_AO_2) \qquad (1)$$

$$= (0.863 \times R \times \qquad)/P_ACO_2 \qquad (2)$$

(The 0.863 constant results from correcting volumes and flows for pressure and temperature conditions)

Equation 2 shows that alveolar ventilation at a given metabolic rate is the unique function of PCO_2 in normal circumstances and therefore, PCO_2 and not PO_2 is the regulating factor of ventilation.[3]

TRANSFER OF GAS ACROSS THE ALVEOLAR CAPILLARY MEMBRANE

Gases pass through the complex structure of the alveolar membrane consisting of the alveolar epithelium lined by lipoproteins, the epithelial basal membrane, the interstitium, the endothelial basal membrane and the capillary endothelium to reach the plasma. Gas enters the membrane by dissolving almost instantaneously either in the lipid layer or directly in the aqueous components of the cells in proportion of its solubility, which varies from very low for helium to high values for diethyl ether, which are at the extremes of the scope of gases utilized in respiratory studies. For a given partial pressure, a soluble gas reaches a higher concentration at the surface within the alveolar cell than a less soluble one. The rate of diffusion will, therefore, be greater. The site of gas exchange within the lung is difficult to define anatomically, but confined to that part of the alveolar membrane bounded by the ventilated alveoli and on the other side by microvessels that contain blood and which is believed to represent half of the alveolar membrane surface.

Other factors that contribute to gas exchange, apart from solubility and surface area, are molecular weight and thickness of the membrane and indeed the difference of partial pressures across the membrane.[4]

The overall transfer rate is:

$$Dm = k\ [(A/d \times s)/\sqrt{M}]$$

Where D is the transfer rate of the gas in volume per unit of pressure gradient per unit of time, k the diffusion coefficient in cm^2 per unit time, A the surface area, d the membrane thickness in cm, s the solubility of the gas in volume/volume per unit gas partial pressure and M the molecular weight of the gas. Dm is generally called the “diffusing capacity” of the gas across the membrane.

$\dot{V}\dot{O}\dot{O}$ $_{A\ 2\ 2}$

To achieve the transfer from alveoli to blood in the case of oxygen and in part for carbon dioxide, the gas after crossing the membrane and reaching the plasma must diffuse from plasma to erythrocytes and then combine chemically with hemoglobin. The gas crosses the erythrocyte membrane by facilitated diffusion due to the migration of hemoglobin molecules between the surface area and the interior of the cells. The reversible reaction by which gas combines to hemoglobin is not instantaneous and the amount of gas bound will depend on the hemoglobin concentration. The overall rate is the product of the reaction rate, the driving pressure, the volume of blood and the blood flow in the microvessels. The transfer rate for the gas from plasma to hemoglobin can be approximated from a complex equation to:

$$D' = \beta Q + \theta V_C$$

Where β is the “capacitance coefficient” in mmol per l of blood per unit of pressure at 37° C, θ the rate of the chemical combination, V_C the capillary volume.

Because Dm and D′ have the dimension of a flow rate per unit of pressure, their inverse have the dimension of a “resistance” so the total resistance offered against the flow of gas from the alveoli to hemoglobin is the sum of the resistance from the alveoli to plasma and from plasma to hemoglobin:

$$1/T_L = 1/Dm + 1/(\beta Q + \theta V_C)$$

T_L is called the "transfer factor" of the lung. The rate at which the gas leaves the plasma to combine with hemoglobin is fast compared to the rate at which it dissolves in circulating blood for carbon monoxide and nitric oxide and to a lesser extent for oxygen so that βQ can be neglected so:

$$1/T_L = 1/Dm + 1/\theta V_C$$

The transfer factor is often called the diffusing capacity, but as demonstrated it incorporates resistive terms related not only to diffusion, but also to chemical bonding, expressing the complexity of the transfer of oxygen from the alveoli to the blood. The speed at which the bonding of oxygen to hemoglobin occurs is relatively fast compared to the time it takes for an erythrocyte to cross the lung, so that it is not a limiting factor in the transfer of oxygen from alveoli to capillaries, at least until blood flow is very high.[5]

The physical properties of oxygen and carbon monoxide in terms of diffusion are not very different. The plasma concentration of CO remains negligible when a small quantity is breathed because of the high affinity of CO for hemoglobin so that the measurement of TLCO is easy and a good approximation of the oxygen transfer factor.[6]

GAS TRANSPORT TO AND FROM THE PERIPHERY

Oxygen Transport by the Blood

The relationship between cardiac output , arterial and mixed venous concentrations of oxygen in blood and oxygen consumption is:

$$= (\dot{Q})\ (CaO_2\text{-}C\bar{v}O_2).$$

The mixed venous concentration ($C\bar{v}O_2$) is the concentration of oxygen in the pulmonary artery, just before cardiac output enters the lung, where all venous blood from the various organs mix together. This equation states that the amount of oxygen consumed by the tissues is the difference between the total amount of oxygen brought to them by cardiac output from the lung ($\dot{Q} \times CaO_2$) and the amount that is left over and brought back to the lung by cardiac output . As stated before, in a normal subject, CaO_2 always reaches its maximum value after lung oxygenation and does not depend on the subject activity unless in extreme situations. Venous blood concentration depends on the organ activity. It varies from one organ to the other.[7,8]

Oxygen is carried in the blood in two forms, dissolved in plasma (1.5%) and combined to hemoglobin (98.5%). The amount of oxygen dissolved in the blood obeys Henry's law for dissolution of gas into liquids. It is proportional to partial pressure, but the dissolution coefficient for oxygen being very low, the amount of oxygen that can be transported per unit of volume of blood and per unit of time is very limited (0.3 ml/100 ml of blood). It is inadequate to cover metabolic needs. This amount rises to 2 ml/100 ml when breathing pure oxygen. The essential mechanism of oxygen transport is chemical reversible bondage to hemoglobin. The total amount of oxygen present in the blood is the sum of the dissolved and combined oxygen concentration (Table 7.2). Dissolved oxygen is usually neglected in most calculations, but dissolved oxygen is the form that allows oxygen to be transferred from erythrocytes to mitochondria in organs. It is also the physical state allowing the measure of PaO_2 by electrochemical methods.

$(\dot{Q} \times C\bar{v}O_2)$

TABLE 7.2: Normal partial pressures and concentrations of oxygen and carbon dioxide in blood

Oxygen		*a*	*v̄*	*(a – v̄)*
PO_2	mm Hg	**91**	**38**	
dissolved	mmol/L	0.12	0.005	+ 0.07
HbO_2	mmol/L	8.60	6.01	+ 2.59

Carbon dioxide		*a*	*v̄*	*(a – v̄)*
PCO_2	mm Hg	**39**	**44**	
dissolved	mmol/L	1.19	1.37	– 0.18
HCO_3^-	mmol/L	19.60	20.96	– 1.36
$HbCO_2$	mmol/L	1.09	1.72	– 0.63
Total	mmol/L	**21.88**	**24.05**	**– 2.17**

a: arterial blood, v̄: mixed venous blood, (a – v̄): arterio-venous difference

Normal adult hemoglobin (Hemoglobin A) is a conjugated protein consisting of four polypeptide chains (globins) and of an iron porphyrin compound (heme). Oxygen binds to the heme in various successive stages, up to four molecules of oxygen per heme. These stages explain the sigmoid shape of the relationship between PaO_2 and oxygen concentration. A small percentage of total circulating hemoglobin is not functional because it is under the form of Methemoglobin (MetHb) or because some carboxyhemoglobin has been formed in the presence of traces of carbon monoxide (HbCO). The normal concentration of hemoglobin is 9 mmol/l, equivalent to 14.6 g/100 ml, and can carry up to 20 ml of oxygen per 100 ml of blood (1.39 ml per gram if only functional hemoglobin is considered, 1.36 ml if total

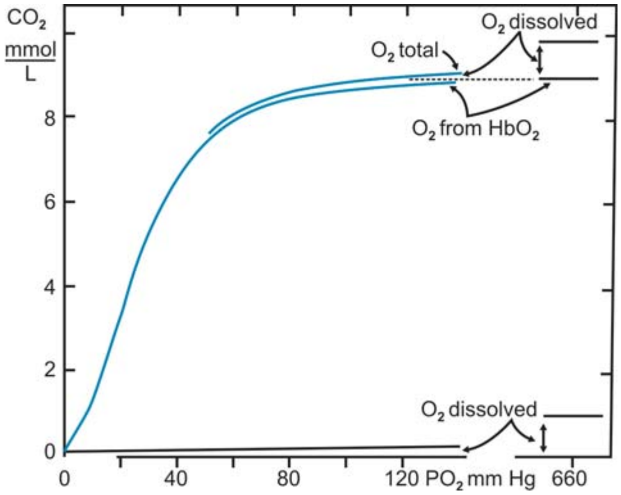

Fig. 7.3: Dissociation curve for oxygen and total oxygen content (CO_2): Total content of oxygen is the sum of oxygen dissolved in plasma and of oxygen combined to blood hemoglobin. Dissolved oxygen is low at atmospheric pressure breathing ambient air, but can rise significantly if ambient pressure (hyperbaric condition) or oxygen fraction is raised (breathing gas with a high oxygen fraction). Content can be given in ml oxygen/100 ml of blood or mmol/L (see Table 7.2)

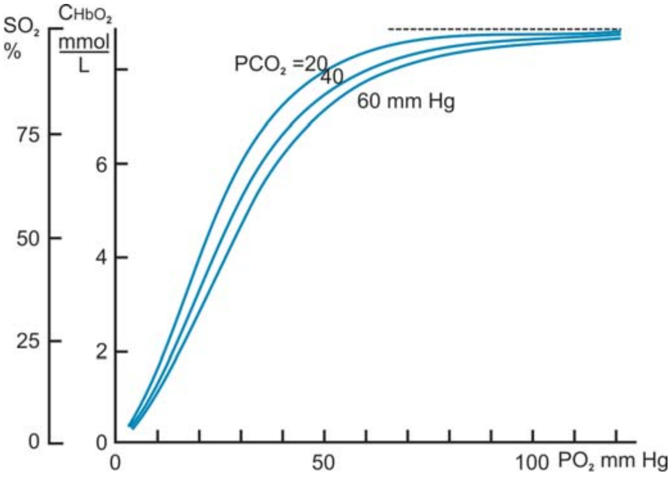

Fig. 7.4: Dissociation curve for oxygen for different PCO_2 in blood: Note that an increase in PCO_2 induces a shift to the right of curve. For the same PO_2 value, less oxygen can be combined to hemoglobin. The process facilitates the release of oxygen to the tissues as metabolism induces a rise of local PCO_2. Note that when hemoglobin concentration is known, the curve is the same for saturation and content

hemoglobin is considered). The maximum volume of oxygen that can be carried by 100 ml of blood is called the total oxygen capacity. The concentration of oxygen in the blood is usually given in ml of oxygen per 100 ml of blood or in mmol/L. It is called the "oxygen content."

The O_2 saturation is defined as the ratio of O_2 combined with hemoglobin (oxyhemoglobin) to O_2 capacity. Normal arterial saturation is 97.5% for a PO_2 of 100 mm Hg at normal temperature and H^+ concentration. Normal mixed venous blood saturation is around 75% for a PO_2 of 40 mm Hg. Because of the sigmoid shape of the concentration and saturation curves (Fig. 7.3), there is no simple relationship between saturation, content and oxygen partial pressure; for example, doubling the pressure does not double saturation. The shape of the curve is beneficial to physiological functions. Because the curve is almost flat in its upper part, a fairly large variation of PAO_2 will not change the loading of oxygen to much extent. The difference in oxygen pressure between blood and alveoli will remain high all along pulmonary capillaries facilitating the rapid diffusion of oxygen between alveoli and erythrocytes. Conversely, because the lower part of the curve is steep, a small drop in pressure will ensure a large flow of oxygen from the erythrocytes to the capillaries and then to the tissues.

The affinity for oxygen of the hemoglobin molecule is modified when its stereo chemical conformation changes, which happens, for example, when $[H^+]$ or PCO_2 changes or when another gas or molecule (carbon monoxide for example) can compete with the O_2 receptor sites.

The hemoglobin dissociation curve is shifted to the right by a rise in $[H^+]$, of temperature and of PCO_2 (Fig. 7.4). This means that under these circumstances, hemoglobin combines with less oxygen and can release more of the oxygen that was already fixed. This facilitates the release of oxygen in organs where metabolism raises the temperature, PCO_2 and $[H^+]$. Organic phosphates present in the erythrocytes (2,3-diphosphoglycerate, DPG) also facilitate the release of oxygen when their concentration rises, as seen in chronic hypoxia (altitude). A useful indicator of the position of the inflexion point of the dissociation curve is the value of P_{50}, the oxygen pressure at which saturation is 50%. The normal value is 26 mm Hg. It is elevated when the dissociation curve is shifted to the left, i.e. when hemoglobin can combine to more oxygen per gram and falls when it can combine to less (right shift).

Oxygen reaches the mitochondria by passive convection and diffusion from the plasma. The P_{O_2} at tissue level and in the mitochondria is very low, but oxygen flow is high. Mitochondrial respiration does not stop until oxygen pressure is at extremely low levels.

The stores of oxygen in the body are very limited, in the form of combined oxygen in the blood (HbO_2) and of MbO_2 in muscles and amounts to 900 µMol/kg of body mass in a normal 70 kg man at rest. These stores allow only a few minutes of survival.

Transport of CO_2 by the Blood

The blood transports carbon dioxide in three forms: Dissolved in plasma; bicarbonate, and in combination with proteins (Table 7.2).

Because the solubility of CO_2 is 20 times higher than that of oxygen, the amount of dissolved CO_2 is more significant in the terms of transport (5% in arterial blood versus 90% for bicarbonates and 5% for proteins).

CO_2 can be transformed in bicarbonate by the following reaction:

$$\begin{array}{c}\text{CARBONIC ANHYDRASE}\\ \downarrow \\ CO_2 + H_2O \quad H_2CO_3 \quad HCO_3^- + H^+\end{array}$$

The speed of transformation of dissolved CO_2 into carbonic acid is very slow in plasma, but greatly facilitated by a specific enzyme, carbonic anhydrase, in erythrocytes. The ionization of carbonic acid occurs quickly and is spontaneously reversible. When bicarbonate concentration increases in the cell, the bicarbonate ion diffuses freely from the erythrocytes to plasma, but H^+ cannot, because the membrane is little permeable to cations. Chloride Ions (Cl^-) move from plasma membrane into the erythrocytes to maintain electrical neutrality in the cells, according to the Gibbs-Donnan equation.

A significant part of the free H^+ can bind to hemoglobin releasing oxygen:

$$H^+ + HbO_2 \rightleftharpoons H^+\text{-}Hb + O_2$$

This facilitates, as said previously, the release of oxygen and the uptake of CO_2 in the tissue capillaries. The facilitation of CO_2 uptake by the release of oxygen in the tissues is called the Haldane effect. The symmetrical facilitation of O_2 uptake by release of CO_2 in the lung is called the Bohr effect.[9]

CO_2 can combine with the terminal amine groups of some blood proteins and in particular with the globins of hemoglobin forming carbaminoproteins and more specifically carbaminohemoglobin (Fig. 7.5). This reaction again facilitates the release of O_2 in the tissues (Fig. 7.6).

Altogether, dissolved CO_2 constitutes 10% of the venous-arteriolar difference for CO_2 against 30% for carbaminoproteins and 60% for bicarbonate.

The dissociation curve for CO_2 differs markedly from the dissociation curve for oxygen. It is steeper than the oxygen dissociation curve for oxygen, especially in 40–50 mm Hg range where CO_2 content varies as much as 4.7 ml/100 ml against 1.7 ml/100 ml for oxygen (Fig. 7.6).

As stated before, CO_2 content increases when the oxygen saturation of hemoglobin decreases, which facilitates gas exchange at the tissue level. The opposite occurs at lung level. Because of these interactions, the gas contents cannot be proportional to partial pressure. This is figured when O_2 and CO_2 dissociation curves are plotted together on a PCO_2 versus PO_2 diagram (Rahn diagram),[2]: The lines of equal O_2 pressure and equal CO_2 pressure (isopleths) are neither straight nor parallel to the axes (Fig. 7.7).

The stores of carbon dioxide in the body are very large because of the high capacitance of all tissues, including the bone. CO_2 is stored mainly in the form of bicarbonates and carbamino compounds. They amount to more than 10,000 µMol/kg of body mass in a normal 70 kg man at rest. These stores change slowly except in the blood and soft tissues so that they can quickly compensate for hypocapnia or hypercapnia.

VENTILATION PERFUSION RATIO

The global efficacy of the lung exchanger depends strongly on the adequacy between alveolar ventilation and capillary blood flow, ensuring that ventilated zones are well perfused, and vice-versa. The relationship between ventilation and perfusion is characterized by the ventilation-perfusion ratio $\dot{V}_A/\dot{Q}$.[10,11] The ratio can be computed from the ventilation equations and the oxygen transport equation in the blood:[12]

$$\dot{V}_A/\dot{Q} = 0.963 \times R\ [(CaO_2 - C\bar{v}O_2)/P_ACO_2]$$

It is noteworthy that this ratio is a function of the respiratory quotient (R). There is a different ratio for each metabolic level (Fig. 7.8). The equation gives the average ratio value for the entire lung. In fact the ratio presents regional variations because ventilation and perfusion are inhomogeneous within the lung (Fig. 7.9). Furthermore, regulation mechanisms, such as hypoxic vasoconstriction may locally modify perfusion and ventilation.

Most of the heterogeneity can be attributed to the effects of gravity on the lung. The influence of gravity on ventilation and perfusion differs in the term of mechanism and amplitude.

The effect of gravity on ventilation is secondary to the elastic structure of the lung. Mechanically, the lung can be seen as suspended to the trachea so that at each level, it is expanded by the weight of its own underlying levels (Fig. 7.10). Consequently, the weight bearing on one level is inversely proportional to that level and

Fig. 7.5: Transport mechanisms for oxygen and carbon dioxide between erythrocytes and tissue (see text for explanations)

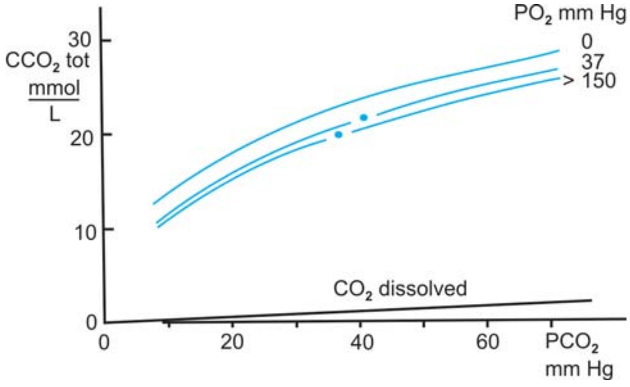

Fig. 7.6: Dissociation curve for carbon dioxide in blood. The shape of the curve is quite flat. The amount of dissolved CO_2 cannot be neglected. A rise in PO_2 induces a shift of the curve downwards. The process facilitates the release of CO_2 in the lungs. This is why there is a shift from one curve to the other, when venous blood looses CO_2 in the lung capillaries and takes up oxygen
a: arterial blood, $\bar{v}$: mixed venous blood
Modified from Dejours[9]

distension increases from bottom to top so that the size of alveoli increases from bottom to top. Because of the relationship between pulmonary volume and transpulmonary pressure, compliance will be lower at the apex compared to bottom so that for a given change of transpulmonary pressure during the ventilatory cycle, ventilation will be higher at the bottom compared to the apex. Alveolar ventilation increases from top to bottom.

The effect of gravity on perfusion is due to the increase in hydrostatic pressure from top to bottom within the elastic vessels of the lung that is not compensated on the external side because the vessels are exposed on that side to the atmospheric pressure of the alveoli instead of a water column that would compensate for hydrostatic pressure at each level as this is the case in the systemic vessels. The rise in internal hydrostatic pressure results in an increase in transmural pressure, so that vessel section rises and perfusion follows. Alveolar perfusion increases from top to bottom.

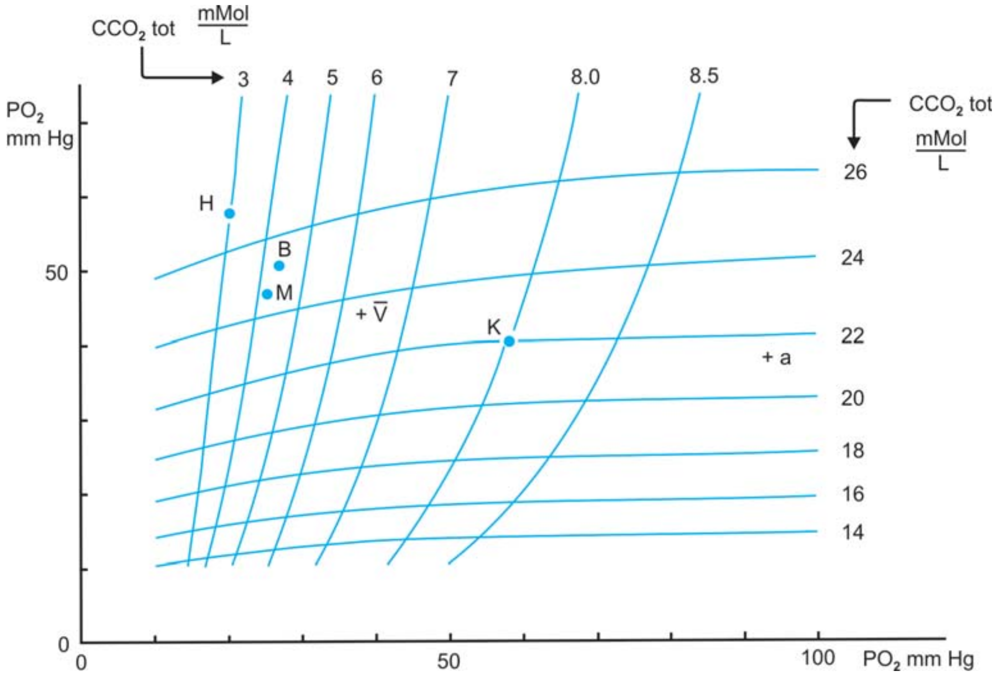

Fig. 7.7: The PO_2-PCO_2 diagram combines the dissociation curves for both gases. The lines represent the isopleths, the pressure curves for one gas at a given concentration of the other one. If there were no interactions between the two gases, all curves for one gas would be flat and parallel to the axis. The changes of partial pressures and of concentrations for both gases can be read on a single diagram when going from arterial to venous blood

Modified from Wagner et al[11]

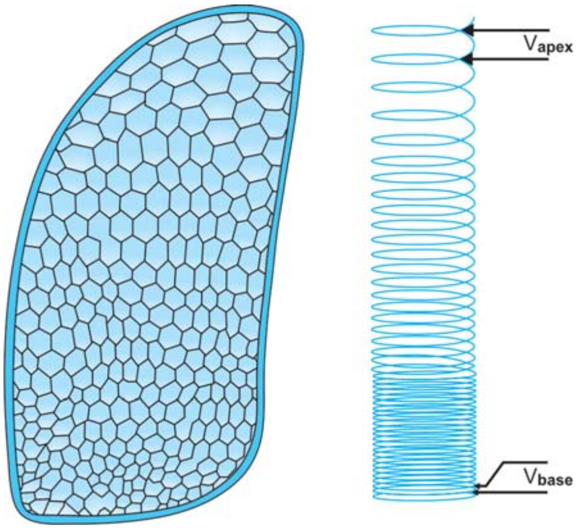

Fig. 7.10: Because the lung behaves like a suspended elastic structure, the weight bearing on any level is that of the structure below it and therefore increases from base to apex. The resulting structure of the lung is pretty much that of a suspended spring. Distension increases from base to apex and so does the volume of the alveoli

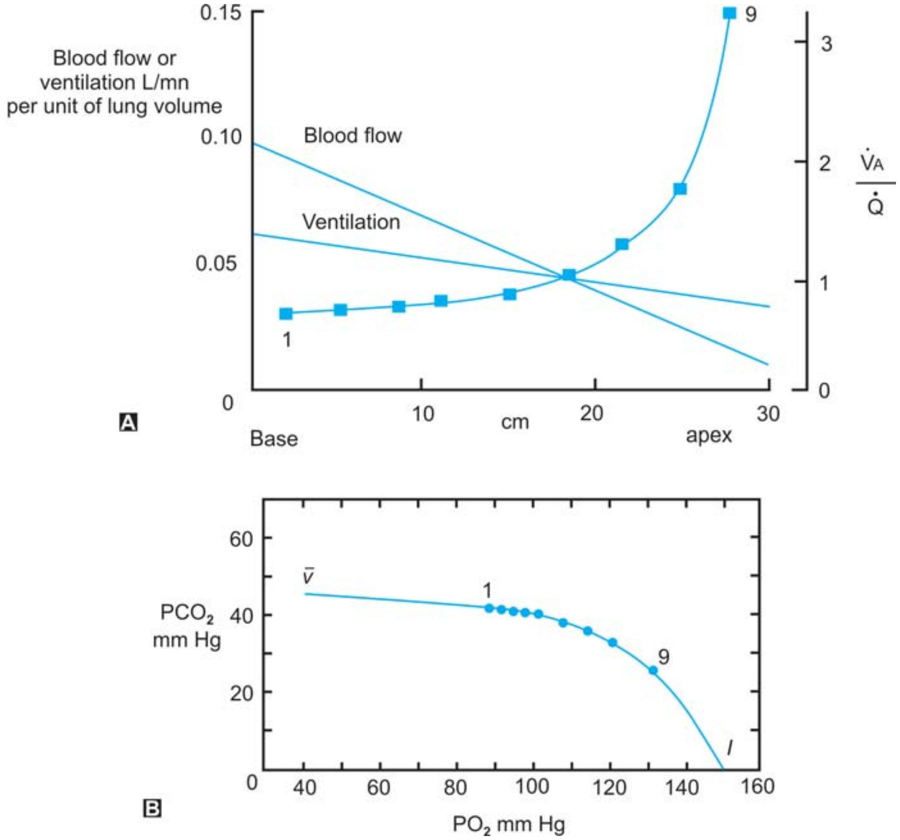
Although, both ventilation and perfusion increase linearly from top to bottom, the increase in ventilation is not proportional to that of circulation. The resulting relationship of the ratio to height is curvilinear (Fig. 7.11A). In theory $\dot{V}_A/\dot{Q}$ may vary from zero (a perfused zone with no ventilation) to infinity (a ventilated zone with no perfusion) (Fig. 7.12). The average lung value is 0.84.

For a given ventilation-perfusion ratio, there is only one possible quantitative relationship between P_AO_2 and P_ACO_2 and thus between P_aO_2 and P_aCO_2. In other words, for any given P_AO_2 or P_ACO_2, there is only one possible P_aCO_2 or P_aO_2. The possible paired values can be represented as a distribution curve on a P_{O_2}-P_{CO_2} diagram (Fig. 7.11B). Each level of the lung has its own $\dot{V}_A/\dot{Q}$ value so that the $\dot{V}_A/\dot{Q}$ of a given level corresponds to a specific paired value (Fig. 7.13).

The range of variation of P_{O_2} is almost of 40 mm Hg against only 14 mm Hg for CO_2. This asymmetrical nature of the distribution curve is a consequence of the very different relationship between pressure and concentration for each gas, relatively flat for CO_2, but sigmoid for O_2 and also because of the predominating role of PCO_2 in the regulation of ventilation. The largest variations of the $\dot{V}_A/\dot{Q}$ ratio are observed in the upper regions of lung. This is mostly due to the fall of local perfusion in these regions. $\dot{V}_A/\dot{Q}$ gets below its average value when going towards the bottom of the lung; the P_ACO_2-P_AO_2 diagram shows little changes in P_ACO_2, but an important drop in P_AO_2. $\dot{V}_A/\dot{Q}$ gets above 0.84 when going towards the apex; P_ACO_2 tends very quickly to very low values while PO_2 almost reaches inspired air O_2 partial pressure. Consequently, the PaO_2 of blood is higher and the $PaCO_2$ lower at the apex compared to the bottom, meaning that blood oxygenation is more efficient at the apex. However, proportionally, most perfusion and ventilation take place towards the base, therefore, most of the alveolocapillary exchange is located there, although it is less efficient.

Gas Exchange and $[H^+]$

The relationship between PCO_2, HCO_3^- and $[H^+]$ implies a close relationship between these parameters and ventilation. In fact, the role of ventilation on pH regulation in the organism is essential. The physiology of gas exchange cannot be fully understood unless acid-base status is known.



Figs 7.11 A and B: (A) Blood flow and alveolar ventilation per unit of lung volume decrease linearly from top to bottom, but not with the same slope. The ratio of one to the other is therefore curvilinear. (B) For each $\dot{V}_A/\dot{Q}$ value in diagram A (1 to 9), everything being equal, there is only one possible pair of PO_2-PCO_2 values as shown in diagram B (1 to 9). The continuous line gives all the possible PO_2-PCO_2 paired values from inspired gas (I) to mixed venous blood (v). Each dot on this line gives the pair corresponding to each of the $\dot{V}_A/\dot{Q}$ dots of figure A.

The end results of ventilation and blood-gas exchange can be shown on the P_AO_2-P_ACO_2 diagram on which the O_2 and CO_2 dissociation curves can be superimposed, the $\dot{V}_A/\dot{Q}$ ratio values and the R lines (Fig. 7.14). The figure shows that when only two of these values are known, all others are fixed. For example, for a given R and a given inspired P_{O_2}, there is only one possible combination of $\dot{V}_A/\dot{Q}$, P_ACO_2, P_AO_2, and R.[2]

FLUID, SOLUTES AND PROTEIN EXCHANGE IN THE LUNG

An average of 300,000 ml of blood flows per hour through the microvessels of a human lung and 299,990 ml reach the pulmonary venous system.[13] Although pulmonary vascular pressure is maintained at a low level, which permits high flow at low resistance, the large endothelial surface area still forms an imperfect barrier, leaking water, small molecules and even proteins in all circumstances. There is therefore a permanent, albeit limited outflow flux of around 10 ml per hour of fluid and proteins towards the lung interstitium (Fig. 7.15). The lymphatic vessels due to the respiratory movements can drain this flow from the interstitium. Normally, fluid is prevented to reach the alveoli from the interstitium because of the very low permeability to fluid of the alveolar barrier and because the lymphatic ducts can generally handle excess fluid, upto atleast 10 times the normal value, so that fluid does not accumulate in the lung interstitium or flood the alveoli.[14]

The liquid and protein exchange in the lung are not confined to the alveolar wall capillaries, but also occurs

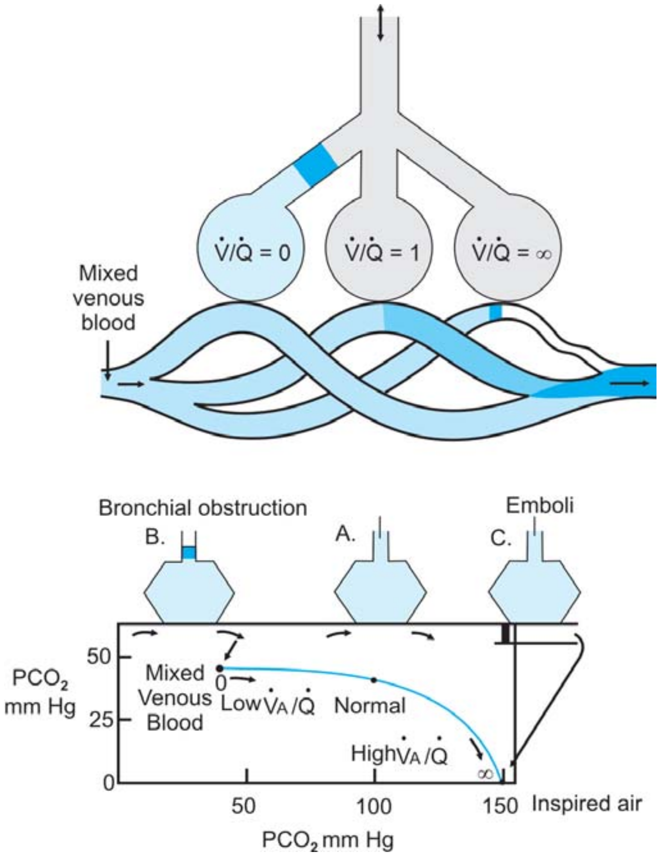


Fig. 7.12: Range of $\dot{V}_A/\dot{Q}$ ratio in case of impaired ventilation and perfusion. In case of bronchial obstruction, there is no ventilation, but perfusion is maintained and mixed venous blood does not participate in alveolar exchange. $\dot{V}_A/\dot{Q} = O$ In case of emboli, there is no perfusion, but ventilation is maintained, $\dot{V}_A/\dot{Q} = \infty$. No blood comes out of the alveoli.

The blood coming out of lung is composed of oxygenated blood from perfused and ventilated alveoli and of mixed venous blood from capillaries that have not been exposed to alveolar ventilation. In normal subjects, the percentage of such capillaries is very low (less than 5%). In fact, they correspond to what is called the physiologic shunt: blood flowing through capillaries that are too far from the alveolar membrane to participate in gas exchange. The physiological shunt explains why saturation cannot reach 100% in arterial blood. In pathological situation, the shunt may increase considerably and lower significantly PaO_2 because more blood flows through the nonventilated area.

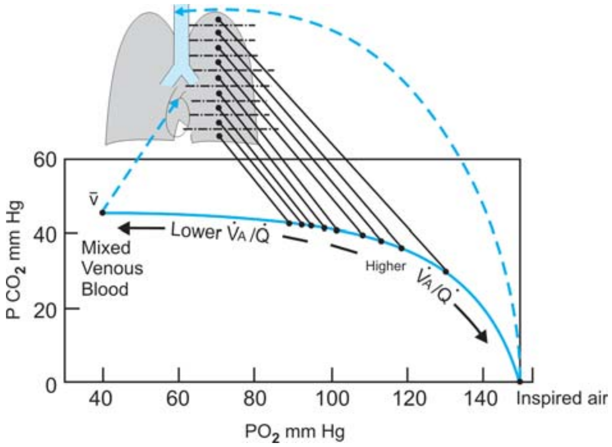

Fig. 7.13: Contribution of the different zones of the lung to the PO_2-PCO_2 curve: The highest $\dot{V}_A/\dot{Q}$ ratios occur towards the apex resulting in high PO_2 and low PCO_2, but most of the perfusion occurs at the base where $\dot{V}_A/\dot{Q}$ is lower. This explains that the average $\dot{V}_A/\dot{Q}$ ratio is 0.84

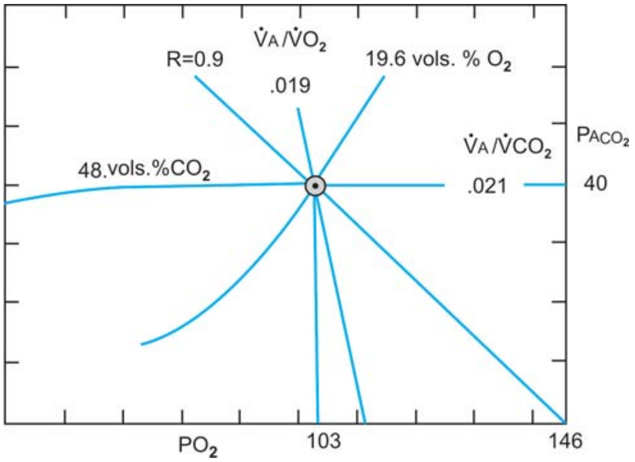

Fig. 7.14: The figure shows that when two parameters are measured all other values are determined. This results from the fact that PO_2 and PCO_2 must be simultaneously on the PO_2-PCO_2 curve, on the R lines and on the corresponding isopleths. Only one point at the junction of all curves satisfies these conditions.
From Rahn et al[2]

in the extra-alveolar lung capillaries[15] and across arterioles and venules up to two generations up or down from the capillary level (Fig. 7.16).

The liquid draining from the alveolar wall to the extra-alveolar connective tissue space does so by a direct route via the alveolar wall junctions. The initial lymphatics are situated in the adventitia of the small extra-alveolar small blood vessels,[16] within the extra-alveolar interstitium, at the junction with the alveolar space (Fig. 7.17). The fluid is drained passively by a hydraulic pressure gradient of about 3 cm H_2O. There is no evidence of any active pumping of fluid from these initial lymphatics to the general lymphatic circulation. The lymphatic flow may increase considerably, up to 10 to 20 folds in correspondence with an increase of the filtration flow at the microvascular barrier.

Fig. 7.15: The lung is composed of three compartments: vascular, interstitial and alveolar.
Because the endothelial membrane is not totally impermeable to fluid and solutes, a continuous flow drains both to the interstitium according to the Starling equation. This net outward flux is drained out of the lung by the lymphatic system. The alveolar compartment remains dry due to the very low permeability of the epithelial barrier. A normal lung contains around 300 ml of water (Q_{wl}). P: pressure; pi: osmotic pressure; mv: microvascular; pmv: perimicrovascular. The osmotic pressure in the interstitium is around 0.6–0.8 that of plasma.
Modified from Blake[13]

Liquid and Solutes Transport

Transport across the microvascular endothelial barrier of the lung is qualitatively similar to that in other organs and obeys the general liquid and solute transport equations.[17] Because permeability to liquid, solutes and to proteins always vary in parallel (a change in permeability to water cannot happen without a simultaneous change in permeability to solutes and to proteins) the basic Starling equation for fluid exchange, which is a simplified expression of these general equations, characterizes reasonably well exchanges through the endothelium:

Fig. 7.17: Lymph drains normally via the lymphatics situated along the arterial, bronchial and venous trees. When lymphatics cannot drain anymore the excess filtration fluid, fluid accumulates first in the loose connective tissues of the bronchoarterial and venous cuffs. Then the alveoli are flooded. The most likely hypothesis explaining alveoli flooding during pressure edema is that overflow occurs in the zone that pumped out alveolar fluid at birth and that may constitute a zone of fragility.
Modified from Staub[16]

Where Q_f is the rate of fluid filtration, P is the fluid pressure, π the osmotic pressure, in the microvascular (mv) and perimicrovascular interstitial fluid compartment (pmv), K_f is the fluid conductance of the microvascular barrier, and sigma (σ), the reflection coefficient of the membrane. K_f is the product of the permeability to fluid and small solutes per surface unit (P) by the surface of the exchange area S. Sigma characterizes the effective osmotic pressure of solutes, i.e. the fraction of solute concentration that cannot be balanced across the barrier because a fraction of the molecules cannot cross the barrier due to restrictive permeability because of size and structure. Sigma = 0 for electrolytes crossing freely and 1 for very large proteins that cannot cross at all. The value of σ in the lung is between 0.6 and 0.8. This implies that the endothelial barrier is not fully impermeable to proteins and results in the fact that the interstitium protein concentration is about 0.8 that of plasma. It is generally believed that more than 95% of filtration fluid flows via the intercellular junctions and is therefore paracellular, and that other passive or active transcellular mechanisms are little related to bulk flow.

Types of Edema

We can deduce from the Starling equation that two types of edema may occur: i. High-pressure edema, also called hemodynamic or abusively hydrostatic edema, and ii. increased permeability edema, also called toxic edema.

In high-pressure edema, the conductance of the membrane to fluid and protein remains normal. The rise in filtration flow results solely from the rise in the difference in pressure across the membrane, due exclusively to the rise of the intravascular pressure. The composition of the filtration fluid remains the same as during normal filtration with a low protein concentration, which is reflected by the low protein concentration of the edema fluid.[18] This type of edema is representative of left ventricular failure, the rise of filtration pressure resulting from the rise in pressure in the left atrium (Fig. 7.18).

In increased permeability edema, fluid and proteins conductance of the endothelium are both modified. As stated before, K_f and σ vary together, but in opposite directions: K_f rises while σ decreases so that both fluid and proteins may move more freely across the barrier. The filtration flow increases even without any rise in pressure and the fluid is rich in protein, up to plasma concentration. This type of edema can be induced, for instance by endotoxin, regurgitation or inhalation of toxic substances such as chlorine.

In both types of edema, as long as the fluid remains interstitial, no apparent change occurs in the epithelium. When alveolar flooding occurs, the epithelium appears to become freely permeable to solutes, including proteins, irrespective of the type of edema so that the composition of interstitial and alveolar fluids are identical.[19] It will be low in pressure edema and almost identical compared to plasma in permeability edema. Therefore, the concentration in protein in the alveolar edema fluid reflects that of the type of edema. This explains why the type of edema may eventually be diagnosed from the protein content of fluid sampled at the trachea level.

In fact in most cases, permeability edema is preceded or associated with a transient or persistent rise of pulmonary arterial pressure inducing an additional rise in filtration and possibly a pressure edema as in endotoxic shock, for instance (Fig. 7.19). When this occurs, the rate of filtration becomes very high,[20] as the rise in filtration pressure is associated with a change in membrane permeability (Fig. 7.20). In practice, this implies that ideally, filtration pressure should be maintained as low as possible when permeability changes are suspected, a requirement conflicting in many cases with the need to sustain cardiac function through perfusion and vasoactive drugs.

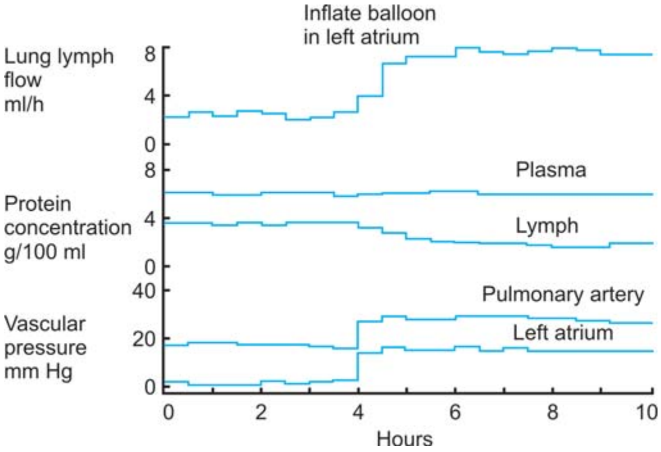

Fig. 7.18: Experimental design showing the effect of a rise in pressure in the right atrium by balloon inflation in a sheep: The rise in pressure in the left atrium causes almost instantaneously a rise in pressure in the pulmonary circulation. The rise of intramicrovascular pressure results in a rise of fluid and small molecules filtration through the endothelial barrier, shown by the increase in lymphatic flow. Because the endothelial membrane remains intact, proteins do not cross the barrier in significant amount and a protein poor fluid filtrates to the lymph so that the ratio of lymph to plasma protein concentration drops with time. This is characteristic of pressure edema.
Modified from Bland et al[18]

Sequence of Fluid Accumulation in the Lung

Clinically, pulmonary edema is defined as the stage when liquid enters the alveolar space. Whatever the type of edema, alveolar filling is believed to be an all or none process, alveoli being filled completely at once. However much before this final and dramatic stage happens, various protective drainage mechanisms offer protection against flooding. The first step for filtration fluid is drainage along the interstitial compartment.

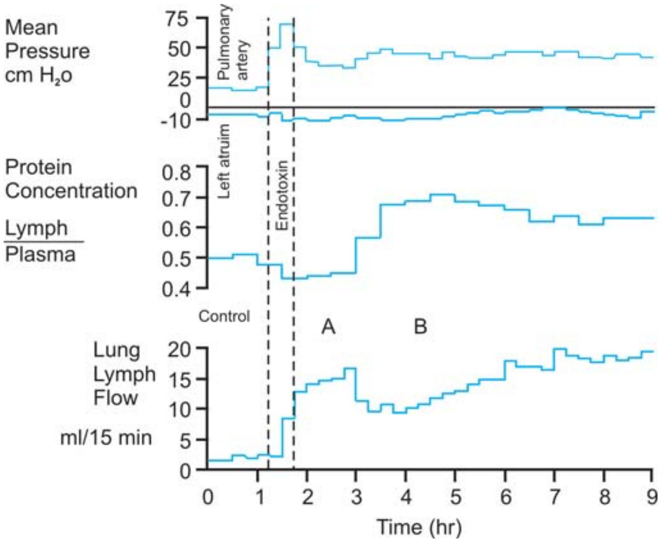

Fig. 7.19: Experimental design showing the succession of pressure and permeability edema in a sheep after administration of endotoxin: In the few hours following administration, pressure rises in the pulmonary artery, lymph flow increases rapidly and the lymph to plasma protein concentration ratio decreases suggesting a typical pressure edema (A). However, if the animal is monitored long enough, pulmonary artery pressure decreases to slightly above normal level, lung lymph, flow increases slowly over several hours to reach a late high plateau, although pressure has remained stable. Lymph to plasma protein ratio which has dropped initially comes back to normal slowly (B). This is interpreted as the emergence of a permeability edema characterized by a moderate pulmonary arterial pressure, a very high lymph flow and a normal lymph to plasma protein ratio suggesting the filtration of plasma and not of a protein poor fluid as in pressure edema. The slow time course is due to the necessary activation of the various biological processes leading to endothelial membrane alterations.
Modified from Robbins et al[19]

Liquid and protein conductance in the interstitium do not depend on the interstitium structure although the constituting matrix structure of the interstitium may vary with pressure and volume. The interstitium does not interfere qualitatively with the fluid when flow increases. This means that the composition of pulmonary lymph is representative of filtration fluid. Interstitial edema happens only at a late stage and is quantitatively limited. The sequence of accumulation of fluid in the lung differs somewhat between hemodynamic and permeability edema. To begin with, in both types of edema, the excess fluid is drained by the lymphatic system until it is saturated, then fluid appears to collect first in the bronchoalveolar interstitial space, the so called bronchial cuffs on the venous, as well as the arterial sides, then in the alveolar wall, and at the corners of the alveoli in the airspace, and finally fills the airspace by a mechanism that is still poorly understood.[16]

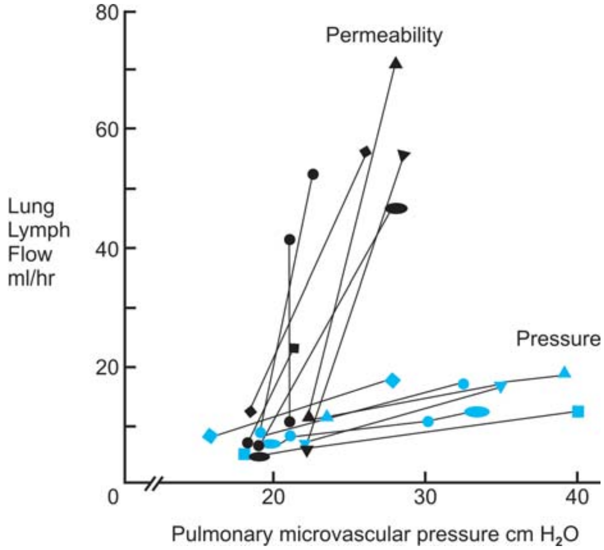

Fig. 7.20: Relationship between filtration flow across the endothelial barrier and membrane permeability in sheep: Black symbols show the change in lymph flow (filtration) with changes in microvascular pressure during permeability edema (endotoxin). Open symbols show the same change during pressure edema (intact membrane). A rise in microvascular pressure results in a dramatic increase in filtration if permeability has been altered simultaneously. A modest rise of filtration pressure in patients with toxic edema can have deleterious effects on the lung.
Modified from Brigham et al[20]

In pressure edema, it is unlikely that direct damage to the epithelium occurs except at very high pulmonary pressure (> 50 mm Hg). Changes in pressure and tension across the alveolar wall cannot explain the overflow because perialveolar interstitial pressure is far too low a driving force to overcome the high epithelial hydraulic resistance. The most likely hypothesis is that overflow occurs at the junction of the alveoli with the first bronchial segments. This zone of so-called natural weakness is precisely where fluids and proteins are reabsorbed from the alveoli to the lymphatics at birth and would play an inverse passive role due to its fragility during pressure edema (Fig. 7.17). In increased permeability edema, direct damage may occur simultaneously to the epithelial and alveolar barrier with fluid filtrating simultaneously to the cuffs and lymphatics and to the alveoli.

Effect of Blood Distribution in the Lung

Blood flow is nonuniformly distributed in the lung on both a gravitational and a local (longitudinal) basis. There is a five-fold variation of flow over the height of the lung due to the action of gravity on distensible vessels. This results in an increasing endothelial surface area towards the bottom of the lung with an increase in filtration that is matched by a proportional increase in the lymphatic drainage structure, so that there is no vertical change in fluid accumulation with height per volume unit. In the case of high-pressure edema, extra vascular fluid tends to accumulate first where pressure and exchange surface per unit volume are highest. This explains the increase in water accumulation from top to bottom. In high permeability edema, the repartition of extra-alveolar lung water is patchy, depending on the repartition of the lesions, and atleast in part, independent of the vertical pressure gradient.

Filtration across the microvascular membrane is linked to the distribution of microvascular pressure and therefore of resistance along the microvessels (Fig. 7.21). Contrary to what occurs in the systemic circulation where the drop in pressure and therefore resistance is localized at the arteriolar level, resistance is distributed longitudinally in pulmonary microvessels and may vary not only at the arteriolar level because of hypoxemia or hypoxia (hypoxemic vasoconstriction), but also all along the vessels[21] in response to various biological or pharmacological agents such as serotonin on the arterial side or histamine on the venules side. Consequently, the filtration pressure at the filtration site is dependent on the distribution of resistance between the prefiltration and postfiltration sites (Fig. 7.22). If the resistance is mostly on the prefiltration vessels, then filtration pressure will be low compared to arteriolar pressure and well reflected by the measure of wedged capillary pressure. If resistance is mostly localized on the postfiltration side, then filtration pressure will be only slightly less than arteriolar pressure, and therefore filtration rate will be high and not evaluated correctly by wedge capillary pressure. Therefore, wedge capillary pressure may underestimate filtration pressure with the risk of under evaluating the outwards flux especially in permeability edema.[22]

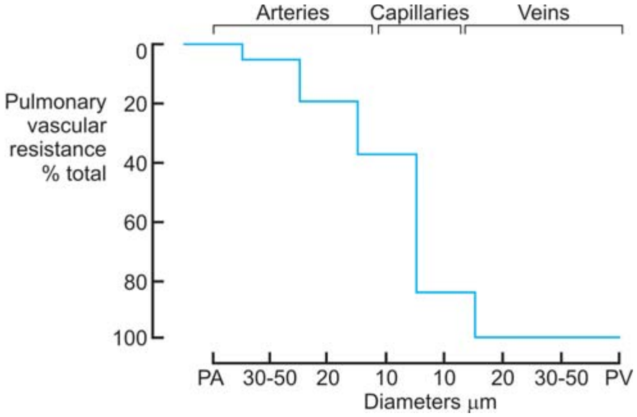

Fig. 7.21: Distribution of vascular resistance in an isolated perfused dog lung: Around half of the total resistance is distributed along the microvessels, a major difference compared to systemic microcirculation where the resistance is located at the arteriolar level.
From Bhattacharya et al[21]

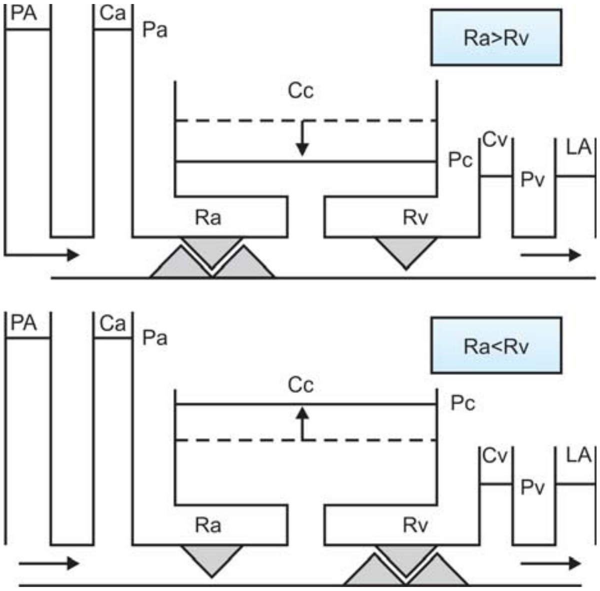

Fig. 7.22: Filtration pressure in the lungs depends on the longitudinal distribution of resistance along the microvessels. When most of the resistance is located prior to the filtration site, microvascular filtration pressure and filtration are low in the filtration compartment (Ra > Rv). When most of the resistance is located past the filtration site, microvascular filtration pressure and filtration are high (Ra < Rv). Pulmonary arterial, arteriolar, pulmonary venous and left atrial pressure are identical in both situations. Wedge capillary pressure may therefore be misleading when taken as an index of true filtration pressure during permeability edema.
AP: pulmonary artery; OG: left atrium; Ca: capillary arterial compartment; Cv: capillary venous compartment; Cc: pulmonary capillary compartment (filtration site).
From Grimbert et al[22]

Filtration through the Endothelial Barrier

The role of the microvascular wall in liquid transport is not passive. Active mechanisms capable of modifying barrier properties have been identified.[23] Some tentative signaling mechanisms that are involved in the regulation of endothelial permeability are shown in Figure 7.23. Solutes can traverse the endothelium via the transcellular and paracellular pathways. The transcellular pathway or transcytosis is a vesicle-mediated transport of plasma proteins across the endothelium by caveolar mechanisms. The bulk of filtration of fluid and solutes occurs across a

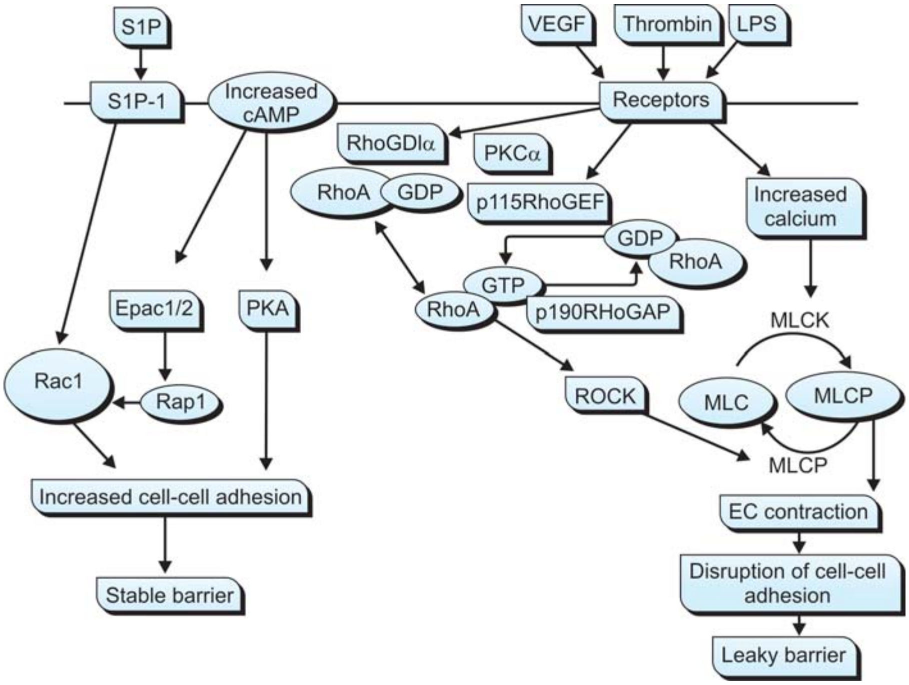

Fig. 7.23: Tentative representation of some of the signaling mechanisms that are involved in the regulation of endothelial permeability: All mechanisms may not apply to the lung microvascular endothelium as phenotypic and genetic variations are known between endothelial cell types, depending on organs and locations in organs.
This representation makes the assumption that a common final pathway exists for various types of receptors (VEGF, Thrombin, LPS). See text for details.
From Vandenbroucke et al[23]

small fraction of the total microvascular surface area formed by the minute intercellular spaces between cells.[24] This space primarily allows the convective and diffusive transport of molecules of less than 3 nm of diameter while restricting, but not totally restricting the passage of larger molecules. The permeability of the interendothelial junction depends on the adhesive properties of the structural proteins of the tight junctions and of the adhesive junctions. These junctions are not passive and can be modified by the endothelial cells in response to specific stimuli acting on them, including sheer stress and pressure changes. The integrity of the junctions is controlled by the actin cytoskeleton through actin remodelling.

Junctional permeability is modulated by inflammatory mediators, for example, thrombin, TNFα and LPS (endotoxin). Mediators act through their respective endothelial surface receptors. Receptor activation increases cytosolic Ca^{++} and activates myosin light chain kinase (MCLK), GTPases RhoA, Racl and Cdc 42. Racl and Cdc 42 reinforce the junctional assemblies while the Ca++ activation of MCLK and RhoA disrupt the junctions, increasing permeability. Other agents, such as sphingosine-1-phosphate and cAMP play a role of barrier stabilizing agents, capable of reducing increased endothelial permeability. The role on permeability of LPS, an endotoxin present on the outer membrane of gram-negative bacteria and a major factor of acute lung injury, exemplify the relationship between the endothelial cell receptors and increased permeability. LPS binds to Toll-like receptor 4, resulting in the translocation of NF-κB to the cell nucleus initiating transcription of proinflammatory mediators, which increase permeability. LPS also promote the expression of an Intercellular Adhesion Molecule (ICAM-1). Cross-linking of ICAM-1 activates RhoA and actin stress fiber formation; ICAM-1 also up regulates RhoA expression, resulting in a positive feedback mechanism on permeability.

Indeed, many other mechanisms may initiate the endothelial cell response such as activation of platelets, the coagulation cascade, neutrophil or macrophage activation, and others. The activation of the inflammatory cascades will be related to the initial cause of disease and takes time to proceed. This explains why the onset of permeability edema is a slow process (hours and days) compared to the onset of pressure edema that can take only minutes to develop. It is important to note that permeability edema may be secondary to the inflammation, secondary to an initial mechanical or chemical aggression, such as thrombi or inhalation of toxic material, which per se does not increase permeability.

Resolution of Alveolar Edema

The first evidence that active ion transport is involved in fluid clearance from the air space was obtained in ventilated, anesthetized sheep. Fluid clearance of an instilled isomolar salt and water solution was shown to occur, although the alveolar protein concentration was rising well above plasma level. It was also shown that reabsorption of protein occurred very slowly and much later than that of fluid by independent mechanisms. Further evidence comes from the inhibition of alveolar fluid clearance in various species, including man by ouabaïn (90%) and amiloride (70%).

The resolution of alveolar edema depends on the active transport of sodium and chloride across the epithelial barrier.[25] Regulation occurs via alveolar epithelial type I and II cells and distal airway epithelia. The differences in hydrostatic and protein osmotic pressures implicated in the Starling equation play no direct role in the removal of excess fluid or proteins. The vectorial transport of sodium, chloride and water is the central mechanism by which alveolar fluid can be cleared at birth, as well as in the mature lung during pulmonary edema. Active sodium transport drives osmotic water transport. Inhibition of sodium transport by appropriate drugs reduces significantly, water transport from the airspace in several species, including man. Isolated epithelial cells have been shown to be capable of actively transporting ions *in vitro*, as well as *in vivo*. Reabsorption can occur at all levels of the distal airspaces; nonciliated cuboidal cells and Clara cells are involved in the mechanisms just as alveolar epithelial cells. They have all been shown to contain the required transporters.

Transport by the alveolar type II cells have been extensively studied because these cells constitute 95% of the alveolar epithelium membrane and because they are fit for *in vitro* studies. Active sodium uptake occurs on the apical cell surface through amiloride-sensitive and amiloride-insensitive channels. Na, K-ATPase pumps sodium actively from the cell basolateral surface to the interstitium. An Epithelial Sodium Channel (ENaC) has been cloned and characterized.[24] Concerning type I cell, studies conducted on fresh cells have identified the expression and presence of $\alpha 1$ and $\alpha 2$ subunits of Na, K ATPase on the basolateral surface of the cell, as well as expression of all subunits of ENaC. The $\alpha 1$ subunit of type I cells has been linked to alveolar fluid reabsorption.[22] Na uptake is sensitive to amiloride blockage. Furthermore, highly selective cation channels have been identified by patch clamp and may participate in fluid clearance.

Water passively follows the sodium-induced fluid movement. The movement of liquid is generally thought to follow intercellular pathways. The identification of specialized water transporting proteins called aquaporins in the lungs has led to the hypothesis that part of the water movement might occur via transcellular channels. The predominant lung aquaporin (aquaporin 5), is expressed in the apical surface of alveolar type I cells, which have one of the highest permeability coefficient for water, leading to the hypothesis that some movement of fluid occurs across type I cells. However, experiments show that the deletion of aquaporin does not seem to affect alveolar liquid clearance.

Endogenous release of catecholamine stimulates the reabsorption of fetal lung fluid from the airspaces at birth. Type I and type II cells both express and present β_2 receptors. Stimulation of these receptors in human lungs by terbutamol, salmeterol or epinephrine increases fluid clearance. This increase can be prevented by nonspecific β_2 antagonists, for example, by propranolol or amiloride. This demonstrates a link between increased filtration, amiloride sensitive sodium transport, and catecholamine dependent regulation of fluid clearance.

Chloride also plays a role in the upregulation of fluid clearance across the distal lung epithelium by mediating cAMP apical uptake of sodium. Cystic fibrosis transmembrane conductance regulator (CFTR) is essential for cAMP mediated upregulation of isomolar fluid clearance from both the distal airways and the alveoli so that CFTR might be the chloride channel involved in the process. Chloride channels are β_2 sensitive.

Various catecholamine-independent mechanisms have also been identified lately, including proinflammatory molecules, such as TNF and leukotrienes D4, some growth and hormonal factors acting by transcriptional or post-translational mechanisms.

CLINICAL IMPLICATIONS

Resolution of pulmonary pressure edema depends on the clearance of fluid from the alveoli, a process that requires a functional alveolar epithelium. The alveolar and distal airway epithelia are remarkably resistant to edema[17] compared to adjacent lung endothelium so that the alveolar barrier may remain functionally intact after endothelial injury. This might explain why in mild to moderate lung injury, the transport of water and sodium may remain normal or even be upregulated by stress hormones.

The rate of alveoli clearance of water has been measured during major pressure (hemodynamic) edema in several species, in ex-vivo human lungs and in patients. It was found to vary from 3% per hour to a maximum of 14% per hour and found to be generally around maximal level providing alveolar epithelium was intact. Clearance was increased in 75% of the patients. In acute lung injury (permeability edema), alveolar clearance is impaired in 56% of the patients and there is a convincing relationship between the clearance rate, extent of epithelial injury and patient's survival. This has encouraged strategies to increase alveolar fluid clearance, essentially by means of β_2-agonist therapy, but also by vasoactive agents (dobutamine, dopamine) and growth factors. However, these strategies can be meaningful only when enough of the alveolar epithelium has remained functional.[26]

MEASUREMENT OF EXTRAVASCULAR LUNG WATER

Quantification of extravascular fluid accumulation may appear a significant tool to analyze the exchange of fluids within the lung. As always in compartmental analysis, the significant approach would be to quantify the net flux of fluid and solutes across the barrier, a technical measurement that is very difficult to obtain, especially in a clinical setting. The measurement of extravascular lung water (EVLW) has been attempted by a variety of single pass indicator, thermal and osmotic dilution techniques based on compartmental models of water and solutes exchange or on washout procedures. All these methods have uncertain specificity and sensitivity and the normal range of EVLW has never been properly established. Major limitations are linked to the change in the distribution of tracers in the lung in function of the distribution of perfusion, perfusion pressure, perfusion of extracorporeal fluids, and repartition of diseased area, all factors contributing to variations of the exchange surface area and volumes of diffusion from one time to the other. Furthermore, only tracer accessible zones can be measured, therefore excluding poorly perfused or ventilated areas, resulting in underestimation. In fact, only radiological imaging methods can detect and localize in a functionally and clinically significant manner the extent and localization of extravascular fluid accumulation although it is not quantitative.[27]

CONCLUSION

Transport of fluid and solutes through the alveolar wall is a complex process requiring the active participation of the endothelial and epithelial cells. Pressure and permeability edema have different characteristics in the terms of time course and cell activation. They may occur simultaneously or successively as in gram-negative infections. Permeability edema provokes much higher levels of filtration, compared to pressure edema, and is extremely sensitive to modest changes in filtration pressure. Filtration pressure tends to be undervalued for the lack of adequate measurement technique. Treatment of pressure edema focuses successfully on the mechanical change in pressure, whereas permeability edema is dependent on our capacity to counteract the inflammatory mechanisms, this with limited success so far because of their complexity.

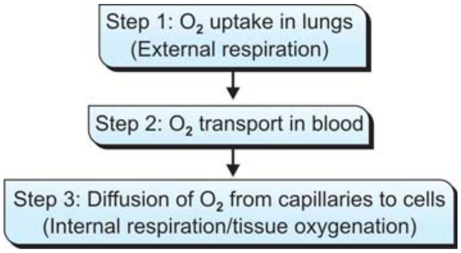
Tissue Oxygenation

Puneet Malhotra, SK Jindal

INTRODUCTION

The final link in the transport of oxygen from the atmosphere to the cells is known as internal respiration or tissue oxygenation, which involves the exchange of gases between capillaries and tissue cells (Fig. 8.1).

More than 90% of the body's oxygen consumption is utilized by a single enzyme, cytochrome oxidase during the process of oxidative phosphorylation, which generates adenosine triphosphate (ATP). This is the most efficient means of producing ATP, since a total of 38 molecules of ATP are generated per molecule of glucose. Aerobic cellular respiration depends on the efficient supply of oxygen to the mitochondria, which is a function of the coordinated interaction between the respiratory and circulatory systems. When oxygen supply is inadequate, anaerobic metabolism sets in and generates only 2 molecules of ATP per molecule of glucose (Fig. 8.2). In addition H^+ ions are formed, which can lead to a systemic metabolic acidosis. Tissue oxygenation is often impaired in critically ill patients, who have poor cardiopulmonary reserve and optimizing oxygen delivery to meet oxygen demand, has the potential to improve outcomes in these patients.



Step 1: O_2 uptake in lungs
(External respiration)
Step 2: O_2 transport in blood
Step 3: Diffusion of O_2 from capillaries to cells
(Internal respiration/tissue oxygenation)

Fig. 8.2: Aerobic metabolism via oxidative phosphorylation in the mitochondria produces 19 times more energy (ATP) than anaerobic glycolysis

The main determinant of tissue oxygenation is a balance between oxygen delivery (DO_2) and oxygen consumption (VO_2). An imbalance between the two results in oxygen debt.

OXYGEN DELIVERY (DO_2)

Calculation of DO_2

Tissue oxygen delivery depends on two factors: i) arterial O_2 content (CaO_2), and ii) cardiac output (Q) (Fig. 8.3).

$$DO_2 = Q \times CaO_2$$

The normal range for DO_2 is 520–570 ml/min/m^2 and under normal physiological conditions, DO_2 is considerably in the excess of the oxygen consumption

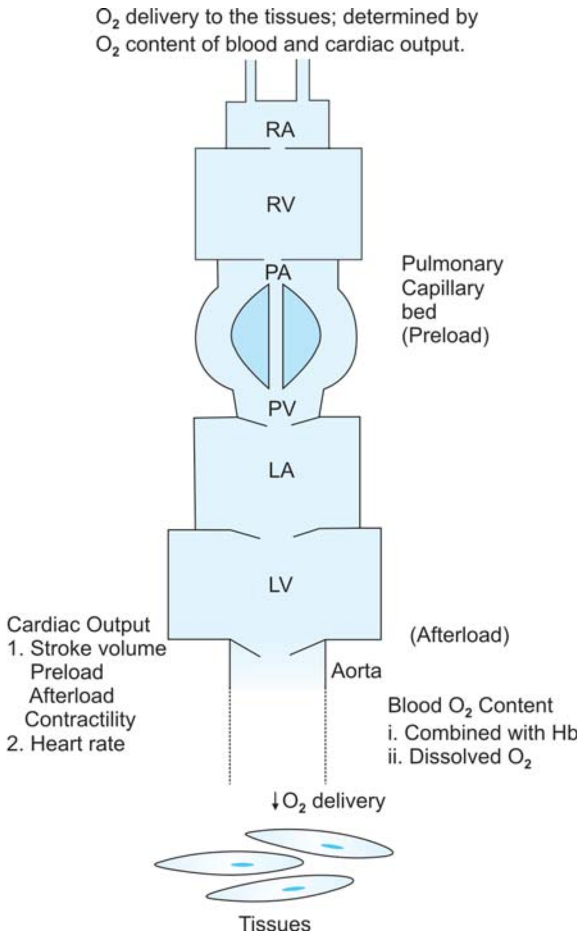

Fig. 8.3: O_2 delivery to the tissues; determined by O_2 content of blood and cardiac output

(110–160 ml/min/m^2). This "spare capacity" enables the body to cope with a fall in oxygen delivery without initially compromising aerobic respiration.

Factors Influencing DO_2

Arterial O_2 Content (CaO_2)

It is the total amount of O_2 present in blood, i.e. combined with hemoglobin (Hb) and dissolved in plasma.

$$CaO_2 = (1.34 \times Hb \times SaO_2) + (0.0031 \times PaO_2)$$

The contribution of Hb is described by the first part of the equation. This relationship states that each gram of Hb will bind 1.34 ml of O_2, when it is fully saturated with oxygen. The SaO_2 is expressed as a fraction, not a percentage (i.e. 1.0 instead of 100%). Therefore, at a Hb level of 15 g/dL and an SaO_2 of 98%, the oxygen carried by Hb will be:

$$1.34 \times 15 \times 0.98 = 19.7 \text{ ml/100 ml}$$

From the second part of the equation one can infer that, at a PaO_2 of 100 mm Hg, the expected concentration of dissolved O_2 in blood is

$$0.0031 \times 100 = 0.3 \text{ ml/100 ml}$$

Therefore, the total concentration of O_2 in arterial blood is 19.7 + 0.3 = 20 ml/100 ml. Thus, it is clear that CaO_2 primarily depends on Hb and SaO_2 and to a lesser extent on PaO_2.

Cardiac Output

In critically ill patients, cardiac output can be measured by invasive, as well as noninvasive methods:

i. *Invasive methods:* These include direct and indirect Fick methods, which require pulmonary artery catheterization and intubation respectively.
ii. *Noninvasive methods:* These include Electrical Impedance Cardiography (EIC) and Transesophageal Echocardiography (TEE).

DO_2 is directly related to changes in cardiac output, which is the product of heart rate and stroke volume. Any alteration in either of these two parameters alters the cardiac output. Stroke volume, the amount of blood ejected per beat is affected by the following factors:

a. *Preload:* It is the load imposed on a muscle before the onset of contraction and is synonymous with the initial length (or stretch) of cardiac fibers. An increase in preload, augments muscle length and leads to a more forceful cardiac contraction (Frank-Starling phenomenon). In fact, in the normal heart, the diastolic volume/preload is the principal force that governs the strength of ventricular contraction. This emphasizes the value of avoiding hypovolemia and correcting volume deficits promptly when they exist. The relationship between preload and cardiac output is however not linear and is also influenced by changes in ventricular compliance and geometry. Since ventricular end-diastolic volume is not easily measured at the bedside; End-Diastolic Pressure (EDP) and Central Venous Pressure (CVP) are more commonly used as reflections of preload in clinical practice.
b. *Afterload:* It is the sum of all forces opposing ventricular ejection. It is influenced by aortic and pulmonary arterial pressures, systemic and pulmonary vascular resistance, and compliance of ventricular muscle. As the determination of these forces is complex, systolic left ventricular pressure is usually used as a reasonable measure of afterload. In addition, since afterload is a transmural force, it is influenced by the pleural

pressures at the surface of the heart. Positive pleural pressures can promote ventricular emptying by facilitating the inward displacement of the ventricular wall during systole and this is one of the mechanisms by which noninvasive positive pressure ventilation is beneficial in cardiogenic pulmonary edema.

c. *Contractility:* It refers to the intrinsic contractile property of cardiac myocytes and is influenced by catecholamine levels, as well as extracellular calcium concentration. Cardiac contractility is measured indirectly by impedance cardiography and Doppler echocardiography.

Steps Involved in DO_2

The final link in the delivery of O_2 to cells, involves two steps: (i) cellular O_2 supply and (ii) cellular O_2 utilization.

i. Cellular O_2 supply: Although all arteries in the body carry virtually identical concentrations of O_2, the distribution of O_2 is not equal to all cells. This is because of the following factors:

a. *Differences in regional blood flow:* The gatekeeper of blood supply to a capillary network is the local arteriole. Arterioles may dilate or constrict in response to various local and central regulatory factors. Local factors causing dilatation include hypoxia, increased CO_2, increased temperature and decreased pH. The release of catecholamines is a central mechanism that attempts to preferentially distribute blood to vital organs when DO_2 is compromised. When the body is confronted with a declining DO_2, both central and local mechanisms are stimulated. In the short term, central effects predominate while if the O_2 shortage persists, local effects override and generalized vasodilatation occurs.

b. *Differences in capillary architecture:* Some cells are simply closer to capillaries than others. Because movement of O_2 depends on pressure gradients, the cells farthest away from capillaries are most vulnerable to hypoxia. In addition, many capillaries are normally closed and open only when perfusion to that particular region increases. For example, an actively contracting muscle may have 10 times more open capillaries than a resting muscle.

ii. Cellular O_2 utilization: Metabolic utilization of O_2 in cells occurs by the oxidation of pyruvic acid in the Krebs cycle (Fig. 8.2). This series of reactions takes place in mitochondria and results in the production of 38 molecules of ATP. The availability of O_2 is crucial in the production of ATP from Adenosine Diphosphate (ADP) in the Krebs' cycle. The actual process of ATP formation is called oxidative phosphorylation as phosphate is added to ADP by using the energy from oxidation. In the absence of O_2, metabolism is less efficient and only 2 molecules of ATP are generated by the metabolism of glucose (anaerobic glycolysis). Furthermore, anaerobic metabolism results in the production of lactic acid, which may lead to systemic metabolic acidosis.

OXYGEN CONSUMPTION (VO_2)

Calculation of VO_2

Oxygen consumption refers to the rate of uptake of O_2 by tissues from the microcirculation. It is a product of the cardiac output and the difference in oxygen content between arterial and venous blood.

$$VO_2 = Q \times (CaO_2\text{-}CvO_2)$$
$$VO_2 = Q \times 1.34 \times Hb \times (SaO_2\text{-}SvO_2)$$

The normal range for VO_2 is 110–160 ml/min/m^2 and it can be measured in three ways:

1. Using Fick's equation given above, which requires the placement of a pulmonary artery catheter.
2. By measurement of inspired and expired minute ventilation (Vi and Ve) and of fractional concentrations of O_2 (FiO_2 and FeO_2) in the two samples. This is a noninvasive method, but is relatively unreliable in mechanically ventilated patients on high FiO_2.

$$VO_2 = (Vi \times FiO_2) - (Ve \times FeO_2)$$

VO_2 can also be measured directly with the help of a rebreathing spirometer system filled with oxygen; the expired CO_2 is absorbed from the system and any change in the volume of gas in the spirometer reflects the VO_2.

Calculated Versus Measured VO_2

The VO_2 is usually derived from Fick's equation and not directly measured. The derivation is based on four measured variables: Cardiac output (Q), hemoglobin concentration (Hb), arterial O_2 saturation (SaO_2) and mixed venous O_2 saturation (SvO_2). Each of these measurements varies and their summed contribution can lead to considerable variability in the final calculated VO_2. Therefore, to be considered a physiologically significant change, the calculated VO_2 should change by atleast 15%.

O_2 Extraction Ratio (O_2ER)

It is the ratio of oxygen uptake to oxygen delivery (VO_2/DO_2), and reflects the fraction of O_2 delivered to the microcirculation that is taken up by the tissues. The

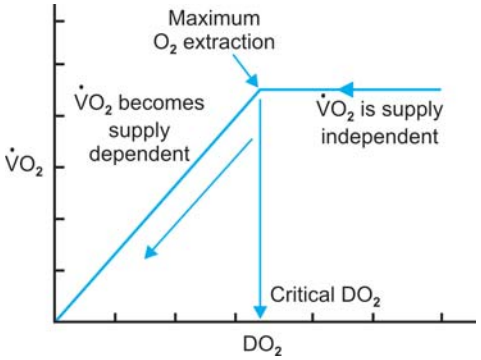

Fig. 8.4: Graph describing the relationship between delivery (DO_2) and O_2 uptake ($\dot{V}O_2$). As DO_2 decreases below normal, O_2 extraction increases proportionally to keep $\dot{V}O_2$ constant and therefore, "supply independent". When DO_2 falls below a critical level, $\dot{V}O_2$ becomes "supply dependent"

O_2ER varies between different organs. For example, the brain has an O_2ER of 34% while exercising muscle can remove all O_2 from its microcirculation and thus have an O_2ER approaching 100%. Overall, the normal O_2ER is 20 to 30%. Thus, only a small fraction of the available O_2 delivered to the capillaries is taken up into the tissues. Oxygen extraction is adjustable, and in conditions where O_2 delivery is impaired, the O_2ER can increase up to 50-60%.

The DO_2-$\dot{V}O_2$ Curve

The relationship between O_2 delivery and O_2 uptake is described by the curve in Figure 8.4. As DO_2 decreases below normal, the O_2ER increases proportionally to keep $\dot{V}O_2$ constant. When O_2ER reaches its maximum level (50 to 60%), further decreases in DO_2 result in proportional decreases in $\dot{V}O_2$. Since under normal physiological conditions, DO_2 is considerably in excess of the $\dot{V}O_2$, tissue oxygenation to a large extent is supply-independent. However, when DO_2 falls below a certain critical level, $\dot{V}O_2$ becomes supply dependent and this condition, in which cellular metabolism is limited by the supply of O_2 is called dysoxia. This *critical O_2 delivery point* (critical DO_2) varies between 150–1000 ml/min/m^2 in critically ill patients, though on an average it is approximately 300 ml/min/m^2. When DO_2 falls below this level, tissue hypoxia ensues, blood lactate increases and prognosis becomes poor. Thus, maintenance of DO_2 in excess of the critical delivery point is crucial in the management of critically ill patients. This is particularly true when Positive End-Expiratory Pressure (PEEP) is being used because PEEP may be associated with a fall in DO_2 despite improvements in PaO_2 because of its effect on cardiac output.

Factors Influencing $\dot{V}O_2$

Causes of Decreased $\dot{V}O_2$

1. *Decreased blood supply to tissues:* Shock (Cardiogenic/hypovolemic).
2. *Cytotoxicity:* An intrinsic defect in O_2 utilization at the cellular level is seen in carbon monoxide and cyanide poisoning, as well as in sepsis.
3. *Increased O_2 demand:* This is seen in most critically ill patients with increased metabolic rates, e.g. acute pancreatitis, burns, etc.

It is noteworthy that tissue hypoxia in sepsis involves all the three mechanisms mentioned above: i) decreased blood supply as a result of redistribution of blood flow due to pathologic capillary dilatation and arteriovenous shunting, as well as microvascular occlusion due to platelet and fibrin microthrombi, ii) disruption of cellular metabolism by cytokines and free radicals, and iii) increased O_2 demand.

Causes of Increased $\dot{V}O_2$

Whenever stress or tissue injury occurs, there is an increase in metabolic rate and $\dot{V}O_2$. In normal subjects exercise increases $\dot{V}O_2$, almost simultaneously with the onset of work. Most of this increase is accounted for by increase in cardiac output. A relative hemoconcentration and therefore increased O_2 content may also occur with the high levels of exercise. The $\dot{V}O_2$ may increase 10 to 15 folds during exercise. In addition, O_2 extraction (see above) may also increase to as much as 80% of $\dot{V}O_2$ in order to meet the additional O_2 requirement. This is made possible by capillary dilatation and recruitment in exercising muscles.

Causes of increased $\dot{V}O_2$ in sick patients include fever, tachypnea, shivering and seizures. In a very ill patient, even innocuous activities, such as chest physiotherapy, getting up or turning in bed and tracheal suctioning can increase $\dot{V}O_2$ and tilt the already precarious O_2 balance.

Oxygen Debt ($\dot{V}O_2$ Deficit)

Oxygen debt or $\dot{V}O_2$ deficit is the difference between the metabolic demand for O_2 and the actual $\dot{V}O_2$. As demand increases, $\dot{V}O_2$ must increase to preserve aerobic metabolism. This is met with by increasing DO_2 either by physiological compensation, e.g. an increase in cardiac output or O_2ER or by therapeutic interventions such as intravenous fluids or inotropes. If this increase in DO_2 is delayed, O_2 debt continues to grow and a stage is reached from where recovery is not possible. Studies of the O_2 debt after resuscitation from hemorrhagic shock and in postoperative patients, show a direct relationship between the magnitude of O_2 debt and the risk of multi organ failure and death. This indicates that the early correction of VO_2 deficits is warranted to limit the severity of tissue ischemia.

ASSESSMENT OF TISSUE OXYGENATION

Unlike hypoxemia, which denotes a low PaO_2 and has standard normal and abnormal values, there are no normal values for tissue PO_2 and it cannot be routinely measured at the bedside. Tissue hypoxia is defined as abnormal O_2 utilization by cells and should be distinguished from other terms, such as hypoxic, anemic, histotoxic and stagnant hypoxia, which can lead to but are not synonymous with tissue hypoxia. There are three ways to detect tissue hypoxia.[4]

Clinical Assessment

Clinical examination should be the first step in assessing tissue oxygenation. A number of well-known signs (mental obtundation, oliguria, abnormal vital signs, delayed capillary refill) often indicate specific organ dysfunction as a sequel of tissue hypoxia. However, clinical signs are often insensitive as they occur late during the course of tissue hypoxia. Direct or indirect measurements of local tissue oxygenation of an organ suspected to suffer from hypoxia will facilitate the assessment. Local tissue oxygen probes have been used in critical care areas in some instances (e.g. brain).

Physiological Parameters

Mixed Venous O_2 Saturation (SvO_2)

Mixed venous blood represents blood returning from all the venous beds of the body, "mixed" together in the right ventricle. It is obtained from the distal end of the pulmonary artery with the help of a specialized pulmonary artery catheter, the tip of which emits infrared light and records light reflected back from hemoglobin in circulating erythrocytes. This technique is called *reflectance spectrophotometry* (whereas pulse oximeters use *transmission spectrophotometry*). SvO_2 can also be measured intermittently by withdrawing blood from the catheter. In the proximal part of the pulmonary artery, blood from the two venae cavae and coronary sinus is not fully blended and therefore does not represent total body venous gas values. SvO_2 is a marker of the balance between whole body oxygen delivery and O_2 demand, and is normally between 65 to 75%, i.e. O_2 demand is usually about 25 to 35% that of O_2 delivery.

Causes of decreased SvO_2

a. Decrease in DO_2: This may occur due to hypovolemia, decreased cardiac output, low Hb, low PaO_2 and SaO_2.
b. Increase in O_2 demand: Critical illness, sepsis, thyrotoxicosis, etc.

Causes of increased SvO_2

a. Increased DO_2: Increased cardiac output (e.g. exercise, use of ionotropes), increased Hb (hypertransfusion).
b. Decrease in O_2 demand: Deep sedation and paralysis in ventilated patients.
c. Decreased tissue O_2 utilization: Cyanide and CO poisoning, sepsis.
d. Left-to-right shunts: These can usually be diagnosed by an abnormal "step-up" of SvO_2 at the level of the defect as the pulmonary artery catheter is passed into the right atrium or ventricle.

A limitation of SvO_2 as a parameter for assessing tissue oxygenation is that normal or increased values do not always mean that tissue oxygenation is adequate. For example, in sepsis and CO poisoning, impaired tissue O_2 utilization results in a normal or high SvO_2. In addition, pathologic vasodilatation and increased cardiac output in sepsis also tend to increase SvO_2 even though tissue hypoxia is ongoing.

Dual Oximetry

By simultaneously measuring SaO_2 by pulse oximetry, one can get a continuous measurement of whole body O_2 extraction, i.e. $SaO_2 - SvO_2$. This method is known as dual oximetry and its normal value is 20 to 30%.

DO_2/VO_2 Measurements

The measurement of changes in VO_2 in response to changes in DO_2 has been suggested as a sensitive method of determining whether tissue hypoxia exists. However it entails multiple measurements at baseline and after various interventions carried out to increase DO_2 (such as the administration of fluids and inotropes) and is therefore impractical.

Biochemical Parameters

Blood Lactate Level

Blood lactate levels increase when tissue hypoperfusion results in anaerobic metabolism. This is known as Type A lactic acidosis and is different from Type B or non-hypoxic causes of lactic acidosis, e.g. delayed clearance of lactate due to liver disease, thiamine deficiency (blocks pyruvate metabolism) and metabolic alkalosis (stimulates glycolysis). A blood lactate value higher than 4 mmol/L is generally taken as abnormal. It is easy to measure and can be followed sequentially to assess prognosis, as well as response to therapy. Recent studies indicate that blood lactate concentrations are a better prognostic indicator than oxygen-derived physiological variables.

Gastric Tonometry

Physiological variables of oxygen transport detailed above and lactate are the indices of global tissue oxygenation and cannot identify oxygen deficits in individual organs. This leads to the development of gastric tonometry to measure regional perfusion in the gut that employs a balloon in the stomach to measure intramucosal pH (pHi). Despite its complexity, tonometry is a reasonably good prognostic indicator in critically ill patients.

Sublingual Capnography

Recently capnography in the sublingual area, a technique that is less invasive and easier to use has been shown to yield tissue PCO_2 measurements that correlate with those obtained by gastric tonometry.

Nuclear Magnetic Resonance Spectrometry

This laboratory technique, not applicable at the bedside, can measure biochemical processes at the cellular level, e.g. levels of ATP, NADH and cytochrome oxidase. Radionuclide imaging, such as Positron Emission Tomography (PET) scanning has emerged as an important tool to characterize tumor oxygenation to optimize and individualize therapy for cancers.

Most of the different parameters of *in vivo* oxygen measurements measure different things and differ in their sensitivity, accuracy and repeatability. It has been proposed that a proper model that relates the various measurements to each other can serve as a powerful tool to assess tissue oxygenation. Unfortunately, such a functional model is not available as yet (Table 8.1).

RECENT DEVELOPMENTS

Hemodynamic monitoring, which relies on physical signs, such as pulse rate, blood pressure, urine output and mentation is inadequate for detecting tissue hypoxia. It has recently been shown that the measurement of central venous oxygen saturation ($Sc\bar{v}O_2$), and its manipulation in patients with severe sepsis has improved survival. In a trial examining $Sc\bar{v}O2$ in severe sepsis, patients with $Sc\bar{v}O2$ levels higher than 70% had lower serum lactate levels, higher pH and base deficit and improved mortality (26% vs 42%). Also, $Sc\bar{v}O_2$ has been shown to correlate well with $S\bar{v}O_2$ measurements and both serum lactate and $Sc\bar{v}O2$ appear to be independent predictors of poor outcome. The advantage of $Sc\bar{v}O_2$ lies in the fact that it can be easily measured by the insertion of a catheter in the internal jugular or subclavian vein, whereas the measurement of $S\bar{v}O_2$ requires the placement of a pulmonary arterial catheter.

TABLE 8.1: Normal values and equations of tissue oxygenation parameters

Parameter	*Equation*	*Normal range*
Arterial O_2 content (CaO_2)	CaO_2 = (1.34 x Hb x SaO_2) + (0.0031 x PaO_2)	20 ml/dL
Cardiac output (Q)	Q = hr x sv	4-8 L/min
Cardiac index (CI)	CI = Q/ BSA	2.4-4.0 L/min/m^2
Oxygen delivery (DO_2)	Q x 1.34 x Hb x SaO_2	900-1000ml/min
Oxygen delivery index (DO_2 index)	DO_2/ BSA	520-570 ml/min/m^2
Oxygen uptake ($\dot{V}O_2$)	Q x 1.34 x Hb x (SaO_2-SvO_2)	180-280 ml/min/m^2
Oxygen uptake index (VO_2 index)	$\dot{V}O_2$/ BSA	110-160 ml/min/m^2
Oxygen extraction ratio (O_2ER)	(SaO_2 - SvO_2/Sao_2) x 100	20-30%

BSA: body surface area; Hb: Hemoglobin; hr: heart rate; PaO_2: partial pressure of O_2 in arterial blood; SaO_2: arterial O_2 saturation, SvO_2: mixed venous O_2 saturation; sv: stroke volume.

Respiratory Physiology in Specific Physiological States

Sunil K Chhabra, Mansi Gupta

INTRODUCTION

The respiratory system performs the essential function of gas exchange and plays its assigned role in the maintenance of the acid-base homeostasis to perfection with its basic mechanisms of the control of breathing, lung mechanics, gas diffusion and transport, and regulation of pulmonary circulation in a coordinated and integrated manner under a wide range of environmental conditions and physiological states of the body. Together with the cardiovascular system and aided by an appropriate response from other systems, the human body can adapt to these variations from the normal state without any adverse consequences. These adaptations may sometimes resemble changes in pathological conditions and hence the knowledge of physiological changes in these specific states is necessary to avoid an erroneous interpretation of symptoms and signs. However, adaptations have a limit in the time course over which they develop and in the range of deviations from the normal resting state at the sea level. Due to these limits, the adaptations may fail and manifest as pathological conditions. The following sections are devoted to changes in respiratory physiology and allied systems in specific physiological states such as exercise, pregnancy, high altitude and deep diving.

EXERCISE[1-14]

While exercising, the muscles are required to perform greater work and thus require more energy. This is provided by increased aerobic metabolism and thus increased oxygen consumption. The oxygen consumption in the muscles increases with the rising intensity of exercise. An integrated response of the cardiovascular and respiratory systems is required to meet the increased demand for oxygen by the muscles and to eliminate the excessive amount of CO_2. This response requires an increase in the heart rate, cardiac output, regional blood flow in the exercising muscles, oxygen extraction by the tissues and ventilation to washout extra CO_2. It is coordinated and related to the workload and meets the requirements of the exercising muscles. The acute respiratory and cardiovascular responses to exercise are complimented by changes and responses in the muscles, as well as neurological and endocrinal systems in an effort to survive through a wide range of severity of exercise without adverse consequences. The physiological changes occurring in the cardiorespiratory systems on exercise are summarized in Table 9.1.

Respiratory System

Increased extraction of oxygen in the exercising tissues results in a fall in the mixed venous PO_2 of blood reaching the right side of the heart, from a normal of 40 mm Hg to 25 mm Hg or even less. This increases the alveolo-capillary gradient, even though the alveolar PO_2 is not changed. As a result, the amount of oxygen entering the blood in the lungs is increased. The increased alveolo-capillary gradient for oxygen is aided by an increase in the diffusion capacity that may be up to threefold on exercise. This results from the recruitment of underperfused pulmonary capillary beds due to increased blood flow and pulmonary artery pressures, thus providing a greater surface area across which oxygen can diffuse into

TABLE 9.1: Physiological changes in the cardiorespiratory systems on exercise

- Increased rate of oxygen consumption
- Increased CO_2 excretion
- Increased alveolocapillary gradient for oxygen
- Increased diffusion capacity
- Increased blood flow and pulmonary artery pressure
- Recruitment of underperfused pulmonary capillary beds
- Increased ventilation
- Decreased airway resistance
- Decreased ratio of Dead Space (V_D) to tidal volume (V_T)
- Rightward shift of the oxygen-hemoglobin dissociation curve
- Increased extraction of oxygen in the muscles
- Dilatation and recruitment of the capillary bed of the muscles
- Increased blood flow to muscles
- Increased arterial blood pressure
- Increased stroke volume
- Increased heart rate
- Increased venous return
- Increased cardiac output

the blood. The pulmonary blood flow increases from a normal of 5.5 L/min to as much as 20–35 L/min.

Those athletes who require greater amount of oxygen per minute have higher diffusion capacities. It is not clear how much of this increase is genetic and how much is acquired through training. Normally, there is a mild degree of ventilation-perfusion inequality due to relative underperfusion in the upper zones of the lung. During moderate exercise, this is reduced because of the more uniform distribution of blood flow in upper zones, providing another adaptation to facilitate oxygen uptake. On the other hand, in athletes performing strenuous exercise, a mild degree of interstitial pulmonary edema related to increased pulmonary artery pressures may develop leading to mild ventilation-perfusion inequality.

The total amount of oxygen entering the blood increases from 250 ml/min at rest to values as high as 3000 to 4000 ml/min. In a marathon runner, it may exceed 5000 ml/min, a 20-fold increase. The rate of oxygen usage under maximal aerobic metabolism is written as Vo_2 max. The Vo_2 max of a marathoner may thus be 40 to 50% greater than that of an untrained person. Training does increase the Vo_2 max, but only to a limited extent of about 10% over two to three months. However, longer periods of training may increase the Vo_2 max further, and it is also probably genetically determined. The oxygen saturation, PaO_2 and the oxygen content of the blood (CaO_2) leaving the lungs remain the same as at rest. This is dictated by the oxygen hemoglobin dissociation curve, as well as the hemoglobin levels. The CO_2 excretion also increases from 200 ml/min to as much as 8000 ml/min.

Oxygen consumption and total pulmonary ventilation at different levels of exercise increase with a linear relationship depending on the intensity of the exercise up to a limit. Above this limit, the aerobic metabolism in the muscles is unable to synthesize energy stores at a pace matching their utilization, and thus anaerobic metabolism sets in (anaerobic threshold). The oxygen consumption levels off, an oxygen debt is incurred and the blood lactate level rises.

Ventilation increases abruptly and sharply with the onset of exercise followed by a further, more gradual increase. The initial rise in ventilation occurs primarily because of an increase in the tidal volume. Though the limit for tidal volume is the vital capacity, it plateaus off at around 50 to 60% of the vital capacity. The tidal volume encroaches into the Inspiratory Reserve Volume (IRV) and, to a smaller extent, into the Expiratory Reserve Volume (ERV). During light and moderate exercise, the contribution of an increase in the respiratory rate to minute ventilation is minimal and gradual. Ventilation decreases abruptly when exercise ceases, and is followed after a brief pause by a more gradual decline to pre-exercise values.

The increase in ventilation is proportional to the increase in oxygen consumption. It is likely that multiple mechanisms are involved in the stimulation of ventilation. The initial sharp increase at the start of an exercise is presumably due to cerebral input to the respiratory center in the anticipation of the increased needs depending on the past experiences and afferent impulses from proprioceptors in muscles, tendons and joints. The subsequent more gradual increase is probably humoral in origin. However, the arterial pH, PCO_2, and PO_2 remain constant during moderate exercise. The increase in body temperature may also play a role. Stimulation of the peripheral chemoreceptors by exercise-induced temperature rise, the plasma K^+ level, increased sensitivity of the neurons controlling the response to CO_2 and increased respiratory fluctuations in arterial PCO_2 (even though the mean arterial PCO_2 does not rise) are some of the proposed mechanisms. Oxygen may also play some role, despite the lack of a decrease in arterial PO_2, since during the performance of a given amount of work, the increase in ventilation while breathing 100% oxygen is 10 to 20% less than the increase while breathing air.

When exercise becomes more intense, there is liberation of CO_2 due to the buffering of the increased amount of lactic acid that is produced in the muscles. This further increases ventilation. With increased production of acid, the increase in ventilation and CO_2 production remain proportional, and thus the change in alveolar and arterial CO_2 is relatively little (isocapnic buffering). The increase in ventilation produced by the acidosis is due to the stimulation of carotid bodies. The alveolar PO_2 increases because of hyperventilation. With the further accumulation of lactic acid, the increase in ventilation becomes out of proportion to the CO_2 production, alveolar PCO_2 and arterial PCO_2 fall. The decline in arterial PCO_2 is a respiratory compensation for the metabolic acidosis produced by the additional lactic acid.

While the level of maximum ventilation achieved is dependent on the intensity of exercise, it is seldom beyond 20 times the resting level, i.e. upto 100 to 110 L. The maximum breathing capacity is about 150 to 170L in an average person. Thus, even on intense exercise, only about 50 to 60% of the reserve is used. There is still sufficient reserve available for extreme circumstances such as exercise at high altitudes and in extreme environments. Further, as oxygen supply from the lungs under normal circumstances is always sufficient, respiratory system response is never the limiting factor for exercise.

The recovery of the respiratory rate after exercise to basal level is delayed until the oxygen debt is repaid. This may take as long as 90 minutes. The stimulus to ventilation after exercise is the elevated arterial H^+ concentration due to the lactic academia. The arterial PCO_2, which is normal or low, or the arterial PO_2, which is normal or high, play no role. The magnitude of the oxygen debt is the amount by which its consumption exceeds basal consumption from the end of exertion until it has returned to pre-exercise basal levels. During the repayment of the oxygen debt, its concentration in muscle myoglobin rises slightly. ATP and phosphorylcreatine are resynthesized, and lactic acid is removed. Eighty percent of the lactic acid is converted to glycogen and twenty percent is metabolized to CO_2 and H_2O. Buffering of lactic acid during strenuous exercise increases the CO_2 liberation and therefore, respiratory exchange ratio (R: the ratio of CO_2 production to oxygen consumption) rises, reaching 1.5 to 2.0. After exertion, while the oxygen debt is being repaid, the R falls to 0.5 or less. Typically, the R rises from about 0.8 at rest to 1.0 on aerobic exercise. This increase reflects a greater reliance on carbohydrate rather than fat to produce the required energy.

Airway resistance decreases owing to bronchodilation as soon as exercise begins. Likewise, the ratio of dead space (V_D) to tidal volume (V_T) decreases. The drop in V_D/V_T is moderate at low-to-moderate exercise intensities. The V_D itself changes minimally with bronchodilation, the change in ratio being largely due to the increased V_T. This is advantageous, as it results in greater alveolar ventilation for given minute ventilation.

Changes in the Muscle

The rate at which oxygen is transported to the mitochondria in the exercising muscle is a limiting factor for the maximum oxygen uptake. As pointed out above, the lungs are never the limiting factor for oxygen uptake in health. During exercise, because of greater oxygen extraction, the tissue and the venous PO_2 drop sharply. There is a dilatation and recruitment of the capillary bed of the contracting muscle, facilitating the delivery of oxygen from blood to cells. The blood flow to muscles during exercise increases markedly, about 25-fold during the most strenuous exercise. This results from intramuscular vasodilatation caused by the direct effects of increased muscle metabolism, and also a moderate increase in the arterial blood pressure on exercise. Muscle contractions temporarily decrease the muscle blood flow by the compression of the intramuscular blood vessels; therefore, strong tonic muscle contractions can cause rapid muscle fatigue because of the lack of delivery of enough oxygen and other nutrients during the continuous contraction.

The oxygen-hemoglobin dissociation curve is steep in the PO_2 range below 60 mm Hg, and a relatively large amount of oxygen is supplied per mm Hg fall in PO_2. Oxygen off loading is further facilitated by the rightward shift of the curve due to the accumulation of CO_2, the rise in temperature and a rise in red blood cell 2,3-diphosphoglycerate (2,3-DPG). The net effect is a threefold increase in oxygen extraction from each unit of blood. As the local redistribution and increased cardiac output result in a 30-fold or greater increase in blood flow, it permits the metabolic rate of muscle to rise by as much as 100-fold during exercise.

Cardiovascular System

The work output, oxygen consumption, and cardiac output during exercise are directly related to each other, linearly. The increased blood flow to the muscles to meet the demand for increased oxygen consumption increases the venous return and hence the cardiac output. Normally, in an untrained person, the cardiac output can increase a little over four fold, and in the well-trained athlete, about six fold. Marathoners can achieve maximal cardiac outputs that are about 40% greater than those achieved by untrained persons. This occurs because of a nearly 40% increase in the cardiac muscle mass, as well as in the size of the chambers, and is observed only in the endurance types, not in the sprint types, of athletic training. At rest, a marathoner with a large heart has the same cardiac output as that of an average person. However, given the increased stroke volume, he can maintain the required cardiac output with a slower heart rate. At rest, a non-athlete person has an average stroke volume of 70–75 ml pumped at around 70 beats per minute while a marathoner has a stroke volume of around 100 ml and thus requires only 50 beats per minute to achieve the same cardiac output.

The increase in stroke volume is also greater on exercise in the marathoner and may reach 150–160 ml (about 50% increases over the resting value). At a maximal heart rate of around 180 beats per minute (up from the resting of 50 beats per minute, an almost 250% change), he will have a much greater cardiac output than a non-athlete in whom the stroke volume increases moderately to around 100–110 ml on exercise. Thus, a marathoner can increase the cardiac output to about 27–30 L per minute while a non-athlete can increase it to around 18–20 L per min. The increase in the cardiac output till about halfway is largely accounted for by the increase in stroke volume and subsequently by the increase in heart rate as the stroke volume gets limited earlier.

During maximal exercise, the cardiac output can reach 90% of its maximum possible value, whereas as noted above, the maximum ventilation achieved is only 50 to 60% of the maximum capacity. Therefore, cardiovascular system is normally much more limiting on V_{O_2} max than is the respiratory system, because oxygen utilization by the body can only be up to the rate at which the cardiovascular system can transport oxygen to the tissues.

PREGNANCY[15-26]

Pregnancy induces major physiological changes affecting all systems of the body. These occur early in the pregnancy and continue throughout gestation, with complete reversal after delivery. Several of these changes would be considered pathological if these were to occur in the nonpregnant state and may even cause symptoms. However, in pregnancy, these changes are considered physiological because they serve to ensure a successful gestation. An understanding of these changes is necessary since inappropriate diagnosis and interventions may occur in the absence of this knowledge. Considering the scope of this chapter, the following discussion is limited to changes in the respiratory system and related cardiological and hematological aspects. These changes are summarized in Table 9.2.

TABLE 9.2: Physiological changes in cardiorespiratory and hematological systems during pregnancy

- Bronchial smooth muscle relaxation
- Reduced TLC, FRC, RV, ERV
- Increased IC
- Increased dead space ventilation
- Increased tidal volume
- Increased respiratory rate
- Increased minute ventilation
- Increase in the oxygen consumption
- Increased blood volume
- Increased red blood cell mass
- Increased left atrial size
- Increased left ventricular end-diastolic dimension
- Increased left ventricular wall thickness
- Increased left ventricular mass
- Increased cardiac output
- Decreased systemic vascular resistance
- Decreased systemic blood pressure
- Increased pulse rate

Respiratory System

Hormonal changes in pregnancy, the increased estrogen, cause edema, capillary congestion and hyperplasia of the mucus glands. It affects the mucosa of the upper respiratory tract, including the larynx, producing hyperemia, mucosal edema, hypersecretion, and increased mucosal friability. This causes the voice to change along with nasal congestion. It leads to the worsening of pre-existing rhinitis. The muscosal changes in the larynx also make endotracheal intubation more difficult, should the need arise. Respiratory infections and pre-eclampsia aggravate these symptoms. As the uterus enlarges, the diaphragm is elevated by as much as 4 cm, the rib cage is displaced upwards and widens, increasing the lower thoracic diameter by 2 cm and the thoracic circumference by up to 6 cm. Abdominal muscles have a decreased tone and are less active during the pregnancy, causing respiration to be more thoracic and less diaphragmatic. The subcostal angle increases from 60–70 degrees to around 100–110 degrees.

Pregnancy causes significant changes in the pulmonary mechanics. The dead space volume increases due to the relaxation of the musculature of the trachea and the bronchi by progesterone. The bronchial smooth muscle relaxation may decrease asthma symptoms in some patients. A state of hyperventilation occurs and the Tidal Volume (V_T) increases gradually (by 35 to 50%) as the pregnancy progresses. The Total Lung Capacity (TLC) is reduced slightly (4 to 5%) by the elevation of the diaphragm. Due to anatomical changes in the thoracic cage, the Functional Residual Capacity (FRC), Residual Volume (RV), and Expiratory Reserve Volume (ERV), all decrease by about 10 to 20%. The increased tidal volume and the smaller residual volume cause an increase in the alveolar ventilation (up to about 65%) during pregnancy.

Inspiratory Capacity (IC) increases by 5 to 10%. Although there is no change in the lung compliance, there is an overall decrease in the chest wall and total respiratory compliance. The Forced Vital Capacity (FVC) is largely unaltered till later in pregnancy as the widened chest diameters counter the effects of the raised diaphragm. Airway function is not affected and FEV_1 remains at the same level as the pre-pregnancy state. The FEV_1/FVC ratio is usually not affected. Therefore, the dyspnea of normal pregnancy is not responsive to bronchodilators.

There are other stimuli that increase the ventilation, including increased metabolic carbon dioxide production, as well as the high serum progesterone that has a direct effect on the respiratory center. The respiratory changes include a slight increase in the respiratory rate, and a progressive increase in the oxygen consumption of up to 15 to 20% above the prepregnant levels by term (due to increased maternal BMR and increased fetal energy demands). With the increase in respiratory tidal volume associated with a normal or increased respiratory rate, there is an increase in respiratory minute volume of approximately 26%. As the respiratory minute volume increases, "hyperventilation of pregnancy" occurs, causing a decrease in the alveolar CO_2. The $PaCO_2$ decreases to around 30 mm Hg in late pregnancy and the renal loss of bicarbonate compensates to maintain the pH in the normal range. This maternal hyperventilation is considered a protective measure that prevents the fetus from exposure to the excessive levels of CO_2.

At the time of labor, the Functional Residual Capacity (FRC) decreases further. The ventilation increases, which is also driven by pain and anxiety resulting in marked hypocapnia and respiratory alkalosis. This may have adverse consequences for the fetus oxygenation by reducing the uterine blood flow. On the other hand, severe pain and anxiety can lead to rapid shallow breathing with alveolar hypoventilation, atelectasis, and mild hypoxemia in some patients. Preoxygenation is less effective and desaturation is likely to occur much faster than in the nonpregnant patient. A preoxygenation period of 3 to 5 minutes is advisable.

Hematological and Cardiovascular Systems

The most striking maternal physiologic alteration that occurs during pregnancy is the increase in the blood volume that varies according to the body mass of the woman, the parity, and the number of fetuses. This occurs due to the effect of progesterone and estrogen on the kidneys, leading to the activation of the renin-aldosterone-angiotensin pathway resulting in renal sodium retention and an increase in the total body water. The increase in blood volume is progressive, starting from the 6th week. The average increase in volume is 45 to 50% by 30–32 weeks; the level being static thereafter till term. The increased volume serves to maintain adequate feto-maternal tissue perfusion, as well as preparing the body to compensate for maternal blood loss during delivery.

The increase in plasma volume parallels the increase in the whole blood volume, the maximum extent being 50%. The red blood cell mass also increases by about 20 to 30%, stimulated by the rise in erythropoietin levels. There is a mild increase in the total leukocyte and platelet count. Simultaneously, platelet consumption is also increased. As plasma volume increases early in pregnancy and at a faster rate than the red blood cell volume, the hematocrit falls until the end of the second trimester, after which the increase in the red blood cells matches the increase in the plasma volume. This hemodilution results in the "physiological anemia of pregnancy." The hematocrit then stabilizes or may even increase slightly near the term. The initial hemodilution is advantageous as the reduced blood viscosity ensures adequate gaseous exchange to the fetus. The increased blood volume also delays the onset of symptoms of hypovolemia in the case of excessive bleeding during delivery. By two weeks postpartum, the hematological changes revert to prepregnancy status.

During pregnancy, as the uterus enlarges and the diaphragm becomes elevated, the heart is displaced upwards and somewhat to the left with rotation on its long axis, so that the apex beat is moved laterally. The cardiac capacity increases by 70–80 ml; this may be due to increased volume or hypertrophy of the cardiac muscle. The overall size of the heart appears to increase by about 12%. The left atrial size increases and correlates with the change in blood volume. The left ventricular end-diastolic dimension increases while the left ventricular end-systolic size might decrease somewhat as a result of the changes in the cardiac contractility. The left ventricular wall thickness increases by 28%, and the left ventricular mass increases by 52%.

A systolic murmur may be audible in the aortic or the pulmonary areas due to hemodilution and torsion of the great vessels. The cardiac output also starts to rise from the 5th week and increases approximately by 30 to

40% at 20–24 weeks gestation, reaches a maximal value of 10 to 30% above baseline values by 32 weeks and continues at this level until term. The cardiac output is lowest in the sitting and supine position and highest in the right or left lateral or the knee-chest position. In the supine position, the gravid uterus may compress the inferior vena cava reducing the venous return to the heart leading to a fall in the cardiac output, maternal blood pressure and placental perfusion. The descending aorta can also be compressed by the uterus causing a reduction in the uterine blood flow. Aortocaval compression is a cause of maternal hypotension from the end of the first trimester onwards, though usually it occurs after 20 weeks of gestation.

The systemic vascular resistance decreases by around 20% due to the effect of progesterone, nitric oxide, prostaglandins and atrial natriuretic peptide. The systemic blood pressure declines slightly during pregnancy. The diastolic pressure is reduced by approximately 5–10 mm Hg from about 12–26 weeks and increases thereafter to prepregnancy levels by about 36 weeks. There is an increase in the pulse rate of about 15 to 25%, a reflex due to reduced blood pressure and extrasystoles may occur. The pulmonary vascular resistance also decreases by 20 to 30%.

During labor, uterine contractions cause a 7 to 25% increase in the maternal cardiac output, a 7 to 15% decrease in the heart rate, and a resultant 7 to 33% increase in the stroke volume. The central venous pressure increases in parallel with the intensity of uterine contractions and increases the intra-abdominal pressure. Additionally, cardiopulmonary blood volume increases by 300 to 500 ml during contractions.

HIGH ALTITUDE[27-42]

Ascent to high altitude represents a physiological stress on the body. The concept of high altitude is arbitrary. Above 1500 m, physiological changes due to hypobaric hypoxia are detectable. With ascent, the barometric pressure falls leading to a lower atmospheric partial pressure of oxygen (PO_2), that in turn leads to a lower alveolar PO_2, although the composition of air remains the same. The pressure at 5,800 m (19,000 ft) is only one-half of the normal 760 mm Hg and the PO_2 of moist inspired gas is 70 mm Hg. On the peak of Mount Everest (altitude 8,848 m, or 29,028 ft), the inspired PO_2 is only 43 mm Hg. At 19200 m (63,000 ft), the barometric pressure is 47 mm Hg, so the inspired PO_2 is zero. Yet, more than 150 million people live at altitudes over 2,500 m (8,000 ft), and even higher than 4,900 m (16,000 ft) in the Andes.

TABLE 9.3: Physiological changes at high altitude

Acute Changes

- Increase in the minute ventilation
- Increase in diffusion capacity of lungs
- Respiratory alkalosis and fall in PCO_2
- Increased pulmonary vascular resistance and perfusion
- Increased heart rate
- Increased cardiac output
- Increase in the regional blood flow by vasodilatation
- Decrease in circulating volume due to water diuresis
- Increase in the number of erythrocytes
- Leftward shift in the dissociation curve

Chronic Effects

- Ventilation diminishes, but still more than at sea level
- Resting $PaCO_2$ increases towards normal, but still low
- Increased vital capacity
- Increased pulmonary vascular resistance and perfusion
- Decreased heart rate
- Increased stroke volume
- Decreased blood pressure
- Cardiac output tends to decrease back to normal
- Increased recruitment of the systemic capillary units
- Increase in the hematocrit values (polycythemia)
- Leftward shift in the dissociation curve

Climbers have lived for several days at altitudes that would cause unconsciousness within a few seconds if the human body did not have the capacity for acclimatization. Respiratory changes and adaptations follow ascent, and are associated with changes in other systems of the body, especially hematological and cardiovascular that allow survival. Table 9.3 summarizes the acute and chronic physiological adaptations on ascent to high altitude. It should be appreciated that these adaptations have regional, ethnic and gender variations. The physiological changes occurring in the body can be classified into acute and chronic, depending on the duration of exposure and stay at high altitude.

Acute Effects of Hypoxia

Respiratory

The minute ventilation increases to minimize the fall in alveolar Po_2 as the barometric pressure decreases. The ventilatory response increases initially on ascent as the PaO_2 falls below 60 mm Hg due to carotid chemoreceptor stimulation, then stabilizes over hours and weeks, and finally declines with deacclimatization on descent. The neural discharge from the whole carotid sinus nerve is related hyperbolically to decreasing Pao_2. Immediately following acute exposure to a very low PO_2, and lasting for perhaps half an hour, a transient "roll off" phenomenon or a hypoxic ventilatory decline may be there. Later, hypoxic stimulation of the peripheral chemoreceptors increases the alveolar ventilation to a maximum of about 1.65 times the normal. The increased ventilation allows alveolar CO_2 to be lowered and thus for a given FiO_2, a higher alveolar PO_2 can be achieved, as dictated by the alveolar gas equation. In extreme cases, ventilation may increase five-fold lowering alveolar CO_2 to as low as 8 mm Hg though usually in high altitude residents at 15,000 ft, it is around 33 mm Hg.

The acute increase in ventilation is inhibited by the resulting respiratory alkalosis and the fall in PCO_2 at the medullary and peripheral chemoreceptors. After a day or so, the Cerebrospinal Fluid (CSF) pH is brought partly back towards normal by the movement of bicarbonate out of the CSF, and after two or three days, the pH of the arterial blood is returned to near normal by the renal excretion of bicarbonate. The inhibition of ventilation is then reduced, allowing it to increase. In addition, there is evidence that the sensitivity of the carotid bodies to hypoxia increases during acclimatization. Over the next two to five days, the chemoreceptors increase the ventilation gradually to over five times the normal. However, the measurement of blood pH has revealed that alkalosis persists as ventilation increases. On the other hand, the cerebrospinal fluid pH may return to normal or even be relatively acidotic, causing sustained hyperventilation. The interstitial fluid around central chemoreceptors has also been found to be acidic inspite of the alkalinity of the CSF. It is possible that some mediator(s), other than H^+, may sustain the hyperventilation during the stay at high altitude.

High-altitude inhabitants exhibit a different long-term response that results in lower ventilation at any given altitude as compared to people experiencing similar altitudes for the first time suggesting that they have a diminished ventilatory response to hypoxia. The vital capacity decreases in the first 24 hours, with an increase in the residual volume and in the slope of the alveolar plateau of the single-breath nitrogen test. These changes are compatible with an increased interstitial fluid volume, resulting in airway narrowing, gas trapping, and delayed emptying of some lung units.

Cardiovascular

The initial increase in ventilation during acute hypoxia is accompanied by an increase in the cardiac output (as much as 30%) and pulmonary perfusion. This helps to sustain oxygen delivery inspite of the decreased arterial oxygen content. The increase in cardiac output is largely a result of an increased heart rate with little change in the stroke volume. This is mediated by an increase in the release of, and sensitivity to, catecholamines that override the augmented parasympathetic tone. Over the next few days at high altitude, the cardiac output decreases, primarily as a result of a decrease in the stroke volume as decreasing plasma volume reduces preload.

The hypoxic pulmonary vasoconstriction causes pulmonary hypertension. The increase in the pulmonary artery pressure starts as the alveolar PO_2 drops below 70 mm Hg, and then sharply below that. This is advantageous as it improves ventilation-perfusion matching by the redistribution of blood flow to areas of the lung that are usually poorly perfused. The increased pulmonary perfusion also improves the diffusion of oxygen.

Hematological

Hemoglobin concentration increases within one or two days of ascent and continues to rise for a number of weeks. The initial rise is due to hemoconcentration following the diuresis that occurs on initial ascent. Later, erythropoietin increases rapidly within 24 to 48 hours to stimulate the red blood cell production and then starts to decline within three weeks as acclimatization progresses. This increase allows the oxygen content to increase even though PaO_2 and saturation are diminished. The erythropoiesis however carries a disadvantage as it also increases the viscosity. There is a rightward shift of the O_2 dissociation curve due to an increase in the concentration of 2,3-diphosphoglycerate following respiratory alkalosis at moderate altitudes, that aids in unloading of O_2 in tissues at a given PO_2. At higher altitudes, there is a leftward shift in the dissociation curve caused by the respiratory alkalosis, and this assists in the loading of O_2 in the pulmonary capillaries.

Chronic Effects of Hypoxia or Acclimatization

Compensatory mechanisms come into play on ascent to high altitudes and allow a person to sustain and work without the deleterious effects of hypoxia on the body. This process is called acclimatization. Ventilation continues to increase for a few weeks. A number of factors, such as regulation of brain pH, metabolic rate and turnover of neurotransmitters, might contribute to this hyperventilation. However, with residence at high altitude, ventilation diminishes, and the resting $PaCO_2$ settles at a higher level, though still lower than at sea-level. This blunting is associated with hypertrophy of the carotid bodies. The decreased energy expenditure of the lower ventilation is an advantage as it reduces the overall oxygen consumption making it easier to sustain at the lower alveolar PO_2.

Chronic exposure causes the vital capacity to increase in high-altitude natives. The increase in vital capacity is dependent on the age at which the subjects start living at high altitude. Natives born at these heights develop larger vital capacities than those who move to high altitude later in life. This is understandable as the lung growth occurs mostly till the age of 8 years. With long-term residence at high altitude, diffusion capacity of the lung increases. This may be due to increased surface area consequent upon higher lung volume and the increase in pulmonary arterial pressure, promoting more blood flow through the alveolar capillaries.

On a prolonged stay at high altitude, the parasympathetic tone plays a role in the decreased heart rate. Downregulation of α-receptors in the myocardium results in lower heart rate on exercise even though norepinephrine levels rise. This does not compromise oxygen delivery as the stroke volume is also increased. The blood pressure is generally lower in high-altitude natives that may be secondary to a primary vasodilatory effect of hypoxia on the arterial wall muscle, as well as its negative inotropic effect on the cardiac muscles. With a more gradual increase in the hemocrit values, lower resting heart rate and higher stroke volume, the cardiac output tends to decrease back to normal. Another hemodynamic change that occurs is the increased recruitment of the systemic capillary units in the nonpulmonary tissues that increases the tissue blood flow and hence the oxygen delivery.

Chronic exposure to high altitude results in an increase in the pulmonary vascular resistance and pulmonary hypertension (primarily at the site of pulmonary arterioles) that may be compounded by polycythemia and hypoxic vasoconstriction and be severe. The continued increase in hemoglobin results from increased red blood cell production (erythropoesis) as part of acclimatization; this adaptation helps sustain oxygen delivery in the presence of a decreased arterial oxygen. In a fully acclimatized individual, the hematocrit may reach 60, with hemoglobin concentration as high as 20 g/dl. The blood volume also increases by 20 to 30%, resulting in a total increase of around 50% in the circulating hemoglobin. This is a slow process and takes many months to complete. These changes increase arterial oxygen content and tissue oxygen delivery.

At high altitude, adaptations occur in the oxygen-hemoglobin dissociation curve that may help facilitate oxygen transfer. Increased 2,3-DPG concentrations have been reported that should result in a right shift in the curve. However, the persistent respiratory alkalosis more than counterbalances the 2,3-DPG effect, shifting the curve back to normal or even slightly to the left. At very high altitudes, a rightward shift of the oxygen-hemoglobin dissociation curve could be a disadvantage for oxygen transport. While favoring the unloading of oxygen from the tissues, the same would also hinder the loading of oxygen in the lungs. A left-shifted curve at extreme altitude would result in enhanced oxygen loading in the lungs and higher arterial oxygen content.

DEEP DIVING[42-56]

Deep diving is done for professional and occupational purposes and increasingly for recreation. The environment on diving changes and has effects on the body systems that can vary from trivial to profound and may sometimes be even fatal if the diver is not careful. In relation to respiration, physiological alterations occur in the breathing cycle and blood gases. There are indirect effects related to alterations in the pressure of blood gases. There occur direct pressure-related problems on descent (including effects on ears, sinuses, thorax, stomach and intestines), and on ascent (air embolism, pneumothorax, mediastinal and subcutaneous emphysema). The effects of the pressure occur especially on compressible fluids, i.e. gas compartments. Pressure has no direct effects on noncompressible tissues and fluids. In addition, there are effects of temperature stimuli. Immersion causes a central redistribution of blood volume, which is increased if cold water triggers vasoconstriction. This reduces Antidiuretic Hormone (ADH) release and results in a diuresis, increasing the risk of hypovolemia on surfacing. The high risk of dehydration is further increased by the breathing of dry gas. Dehydration increases the susceptibility to diving related illnesses. Another challenge is that of temperature regulation. Water has a high thermal conductivity and capacity and the cold water predisposes the diver to, the risk of hypothermia.

Physical Principles in Deep Diving

It would be useful to review some basic laws of physical sciences to understand the diving physiology and associated abnormalities. The effect of diving deep into the sea stems from the tremendous increase in the hydrostatic pressure on the body. The human body is normally exposed to a pressure of 1 Atmospheres Absolute (ATA) at sea level. Water being far denser than air, for every descent of 33 feet, an additional pressure of 1 ATA is added. This is equivalent to 1.013 bar, 760 mm Hg or 14.7 psi. Thus, at 33 feet, the body is exposed to a pressure of 2 ATA, 1 ATA of pressure caused by the weight of the air above the water and the second by the weight of the water itself.

The increase in pressure causes a decrease in the volume of body cavities containing gases in accordance with the Boyle's law, i.e. the volume of gas is inversely proportional to the pressure it is subjected to, with the temperature remaining constant. Thus, compression (i.e. increased pressure) on descent will decrease the volume. If volume of a compartment is expressed as 100% at 1 ATA, it would be 50% at 2 ATA and 33% at 3 ATA and so on. Thus, proportional reduction is greatest in shallow water, i.e. the volume halves at 33 feet. The compression of the air pockets can be extremely dangerous and the lungs are especially vulnerable. An actual volume of 1 liter at a depth of 300 feet is the same quantity of air at a sea-level volume of 10 liters. Deeper a subject goes under the sea, the greater is the compression. To keep the lungs from collapsing, air must be supplied at very high pressure to keep them inflated. This exposes the blood in the lungs also to extremely high alveolar gas pressure, a condition called "hyperbarism." Beyond certain limits, these high pressures can cause tremendous alterations in body physiology, and can be lethal.

The individual gases to which a diver is exposed when breathing air, are *nitrogen*, *oxygen*, and *carbon dioxide;* each of them at times can cause significant physiological effects at high pressures. Even gases, such as carbon monoxide that normally are in negligible concentrations, can pose hazards when their alveolar pressures are increased. Dalton's law states that the total pressure exerted by a mixture of gases is equal to the sum of the pressures of each of its constituent gases, i.e. partial pressures of each gas added up make the total pressure of the mixture. Thus, if the total pressure increases with descent, pressures of body gases in their compartments will also increase proportionately without any change in their concentrations. Henry's law states that at a constant temperature, the amount of gas that will dissolve in a liquid is directly proportional to the partial pressure of that gas at its surface. The amount also depends on the solubility coefficient of the gas. Thus, gases will increasingly dissolve in body fluids on descent depending on their solubility and on ascent, these will bubble out as the pressure decreases. This is the physical principle underlying Decompression Sickness (DCS), described later.

Increased pressure on descent, reduces the volume and increases the density of gases in the airways. This, combined with immersion, reduces pulmonary compliance, increases airways resistance and also results in increased $\dot{V}/\dot{Q}$ mismatch, and an increase in the work of breathing. This increase in the work of breathing is one of the factors, which limits maximum diving depth and along with breath-holding (apnea) is responsible for dyspnea. The combination of resistive and elastic loads is also responsible for the reduction in ventilation. Further, there is a density-related increase in dead space/tidal volume ratio (Vd/Vt), possibly due to the impairment of intrapulmonary gas phase diffusion and distribution of ventilation. The net result of relative hypoventilation and increased Vd/Vt is hypercapnia. Professional divers, therefore, breathe helium-oxygen mixtures that are much less dense and have reduced viscosity compared with air. The concentrations of oxygen and CO_2 do not change except when the breathing apparatus is faulty or of poor design causing CO_2 rebreathing.

Depth and Nitrogen Narcosis

About 80% of the air is nitrogen. At sea-level pressure, the nitrogen has no significant physiological effects. However, at high pressures it can affect the functioning of the central nervous system, an effect called "nitrogen narcosis." The relation of depth to narcosis is sometimes informally known as "Martini law" as the symptoms of nitrogen narcosis resemble those of alcohol intoxication, developing roughly after 66 feet at the rate of the effect of one martini after every 33 feet. When the diver remains beneath the sea for an hour or more and breathes compressed air, the depth at which the first symptoms of mild narcosis appear is about 100–120 feet. Rarely, the effects may be seen with shallow dives. Individuals vary in their susceptibility. However, the problem is universal and related to the depth reached. Tolerance does not develop. The condition is entirely reversible on careful ascent.

Physiological Basis of Oxygen Toxicity

Oxygen is transported in blood largely bound to the heme portion of hemoglobin and to a much smaller extent dissolved in the blood, 0.0031 ml per mm PaO_2. Normally, at a PaO_2 of 100 mm, only 0.3 ml oxygen is dissolved in the blood, physically. When the PaO_2 in the blood rises above 100 mm Hg, the amount of oxygen dissolved in the water of the blood increases several-folds. While the amount bound to hemoglobin is limited due to the saturation of the binding sites, the increase in oxygen content is largely due to an increase in the dissolved oxygen. At an alveolar PO_2 of 3000 mm Hg (4 ATA), each 100 ml of blood contains 29 ml oxygen, 20 ml bound with hemoglobin and 9 ml dissolved in the blood water. The tissues take up their normal requirement of 5 ml leaving 24 ml of oxygen still in the blood. At this point, the PO_2 is approximately 1200 mm Hg, which means that oxygen is delivered to the tissues at this extremely high pressure instead of at the normal value of 40 mm Hg. The normal, safe range is between 20 and 60 mm Hg.

Pathogenesis of Decompression Sickness (DCS) (Caisson Disease, Dysbarism)

An increase in the alveolar PN_2 increases the dissolved nitrogen in the capillary bed, resulting in the same level of tissue PN_2. As nitrogen is not metabolized by the body, it remains dissolved in all the body tissues. However, when the alveolar pressures return to normal, the excess nitrogen is removed by the reverse process from the tissues. This removal often takes hours to occur and is responsible for a constellation of symptoms called "decompression sickness." (Details in Chapter 105).

At the sea level, almost exactly 1 liter of nitrogen is dissolved in the entire body, slightly more than one half of this is dissolved in the body fat, and the remaining in water, nitrogen is five times as soluble in fat as in water. After complete saturation, there is an increase of 1 L equivalent of sea-level volume of nitrogen dissolved in the body for every 33 feet depth. Equilibration of the pressure of nitrogen in all the body tissues with that in the alveoli occurs slowly as several cycles of blood flow are required and the nitrogen diffuses slowly. The equilibrium is complete in less than one hour, but takes much longer in fat tissue because of poor blood supply. For this reason, longer stay will allow more nitrogen to enter tissues at the same depth than a shorter stay. However, if large amount is dissolved due to a long stay, and the diver ascends quickly to surface, due to sudden fall in the pressures to 1 ATA, nitrogen (and to a small extent, other gases) move out of the liquid phase quickly and these cannot be transported to lungs fast enough to be exhaled out. Significant quantities of nitrogen bubbles can develop in the body fluids either intracellularly or extracellularly and can cause minor or serious damage in almost any area of the body, depending on the number and sizes of bubbles formed; this is the mechanism for decompression sickness and follows the Henry's law described above.

Direct Effects of Pressure: Barotrauma

Sinuses and Middle Ear

Noncommunicating spaces are susceptible to the effects of pressure with damage occurring during compression ("squeeze") or due to gas expansion on ascent. In the paranasal sinuses with blocked ostia or middle ears with blocked eustachian tubes, descent of as little as 1–2 m is enough to cause pain, edema and even hemorrhage. Though common, middle ear barotrauma is usually minor and self limiting. More serious injuries such as tympanic membrane rupture can occur. Differential ear equalization can result in alternobaric vertigo that is usually transient.

Pulmonary Barotrauma and Arterial Gas Embolism

Pulmonary volumes remain nearly normal while diving with breathing apparatus, but during ascent, the compressed gas in the lungs expands with the falling ambient pressure. Excessive transpulmonary pressures result if intrapulmonary gas is prevented from escaping as a result of a closed glottis, bronchospasm or gas trapping. If the rate of gas efflux from the lungs is slower than the rate of gas volume change, it will precipitate pulmonary overexpansion, and can happen in uncontrolled ascent from scuba diving at the depth of 3 feet or more. Because of the heterogeneity of compliance, there are differences in the expansion of adjacent lung units causing focal shearing between vessels and airways, and rupture of small airways and/or alveoli. This may result in pneumothorax, mediastinum and subcutaneous emphysema and pneumopericardium. When the air enters pulmonary venules, it reaches the left heart resulting in arterial gas embolism.

Mechanisms of Dyspnea in Respiratory Diseases

Sunil K Chhabra, Ashima Anand

INTRODUCTION

Respiration is an automatic process, that however can be modulated voluntarily. The respiratory drive originates in the respiratory center in the brainstem with inputs from the periphery, as well as the cerebral cortex. Normally, the sensation to breathe and the effort of breathing do not reach a person's consciousness. However, in certain physiological conditions and in pathological states, a person may become aware of his breathing activity.

The term "*Dyspnea*" is used to imply an uncomfortable and unpleasant awareness of an increased effort to breathe. It is a symptom, not a sign. Due to its subjective nature, dyspnea will only have a modest or no relationship with an objective measure of the functional disability of a patient. Therefore, there are no objective surrogates for dyspnea and the patient is the prime source of information. The symptom of exertional fatigue must be distinguished from dyspnea.

DEFINITIONS

The American Thoracic Society has defined dyspnea as "a term used to characterize a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiological, psychological, social and environmental factors, and may induce secondary physiological and behavioral responses."[1]

Certain other terms used to describe alterations in respiratory rate, depth and rhythm may be associated with dyspnea. These have different clinical connotations and are not synonymous. *Tachypnea* is a rapid respiratory rate, greater than the normal frequency of 12–18/min. It may be present with or without dyspnea. Conversely, a dyspneic patient usually has tachypnea on physical examination. *Hyperventilation* is minute ventilation that is greater than what is required to maintain a normal arterial CO_2. Thus the subject will have hypocapnia, but may not be dyspneic. *Orthopnea* or shortness of breath on assuming the supine position, results from an increase in the venous return and pulmonary blood flow that in patients with heart failure causes an increase in the left atrial and left ventricular filling pressures, leading to pulmonary vascular congestion and interstitial or alveolar edema. This is also referred to as "cardiac dyspnea." *Platypnea* is the shortness of breath when the patient is in the upright position and is a rare symptom associated with orthodeoxia (hypoxemia on standing) occurring in pulmonary or intracardiac shunts. *Trepopnea* is the shortness of breath when the patient lies on his or her side and can be relieved by moving to the opposite lateral position. *Paroxysmal nocturnal dyspnea* is waking up from sleep due to dyspnea and is usually a symptom of heart failure. As with orthopnea, the recumbent position is important, but this symptom differs in that breathlessness does not occur soon after lying down. The mechanism and the clinical implications are however similar with the increase in intrathoracic intravascular volume occurring due to a slow mobilization of tissue fluid such as peripheral edema. Patients with asthma and even Chronic Obstructive Pulmonary Disease (COPD) may also have disruption of sleep due to dyspnea. However, the mechanisms are different from those in heart failure.

PERCEPTION: THE SUBJECTIVE ELEMENT IN DYSPNEA

Dyspnea being a sensation, areas in the cerebral cortex concerned with perception must come into play. Indeed, the definition of dyspnea translates into a perceived unpleasant difficulty with breathing. In contrast to the physical stimuli, such as touch, pressure or temperature that are sensed by the peripheral nervous system and perceived as such by the cerebral cortex, the sensation of dyspnea is a central translation in the cerebral cortex of inputs of different nature from several peripheral sites to the respiratory center. The central cortical processing of the information from the respiratory center is modulated by psychological, behavioral and cultural factors that determine a person's ability to sense the stimulus and respond to it. This ability to sense constitutes "perception," a complex behavioral phenomenon that imparts to dyspnea, its subjective quality.[1]

The appropriate qualitative and quantitative feeling or perception of breathlessness in response to a stimulus of a particular strength and nature is impossible to define. A patient of asthma with severe airways obstruction may be asymptomatic, failing to sense the stimulus arising out of severe bronchospasm while another patient with a milder degree of airways obstruction may be very dyspneic, responding to the milder stimulus in an exaggerated manner. The former situation carries the risk of undertreatment, and the latter, overtreatment. The standards of patient care today recognize that monitoring of patients using objective outcomes, such as lung function has limitations, and, patient-reported outcomes that reflect the impact of disease on the person and on daily activities are equally, and perhaps, more important. Dyspnea is a major determinant of the person's response to his ailment, activities of daily living, functional capacity, and hence, the quality of life.

Dyspnea may occur in a variety of respiratory and cardiac conditions, both acute and chronic, as well as in other pathological states, such as anemia, thyrotoxicosis and psychiatric illness, and also in certain physiological states. Differences are expected among patients with regards to the intensity of the stimulus that will cause dyspnea, the language used to describe the sensation, as well as the psychological and physiological response to it. It is necessary for the physicians to appreciate that there are qualitative and quantitative differences in dyspnea in patients with different diseases. The underlying pathophysiological factors responsible for the sensation of dyspnea differ. Therefore, a uniform approach to treating dyspnea cannot be adopted. Management based on an understanding of the underlying mechanisms is more scientific.

While animal studies can provide information about the ventilatory responses under experimental conditions simulating physiological abnormalities encountered in different disease states, such as increased resistive or elastic loads, altered hemodynamics and blood gases, the subjective nature of dyspnea can be studied only in humans. The mechanisms have been investigated in patients with different diseases, as well as in normal subjects under the conditions of mechanical loading or altered oxygenation and acid-base milieu. Instruments have been developed and validated for the quantification of dyspnea. In recent years, there has been a further refinement of methodologies for assessment and quantification of dyspnea and understanding the neurophysiologic mechanisms that may contribute to its genesis. The availability of techniques, such as Positron Emission Tomography (PET) and functional Magnetic Resonance Imaging (MRI) have provided a means to study the central neuronal activity. Yet, the complex nature of the sensation of dyspnea and interplay of several neural pathways in concert makes it extremely difficult to design studies and provide definitive proofs of the responsible mechanisms. The information in literature is therefore often contradictory, controversial and, sometimes, even speculative.

NEURAL PATHWAYS OF DYSPNEA

The neural pathways regulating respiratory activity have been studied extensively and a vast amount of literature is available in this area.[2] The respiratory drive originates from the neurons in the medulla, called the respiratory center. The motor output travels to the diaphragm and the inspiratory muscles leading to their contraction, and, inflation of the chest wall and the lungs. The gas exchange and transport of oxygen and carbon dioxide are intimately involved in the regulation of acid-base balance. Changes in oxygen and carbon dioxide tensions in blood are sensed by central chemoreceptors in the medulla and peripheral chemoreceptors in the carotid and aortic bodies. Signals from these chemoreceptors are transmitted back to the brainstem respiratory centers that adjust breathing to maintain blood-gas and acid-base homeostasis. Mechanoreceptors in the airways, lungs and chest wall provide sensory inputs to the respiratory center on the changes in lung volumes and tissue displacement. Muscle spindles are abundant in the intercostals muscles and the diaphragm contains tendon organs that signal muscle tension and exert inhibitory influences on central respiratory activity. These provide feedback information about changes in the length and force of contraction of the respiratory muscles in response to the motor output. Afferent impulses from vagal receptors in the airways and lungs convey information on several aspects of lung physiology. These include impulses from pulmonary stretch receptors (lung expansion), irritant receptors around the epithelial cells of the bronchial walls (activated by irritants, high rates of air flow, and increases in bronchial smooth muscle tone) and C fibers, found in the interstitium of the lung in proximity to the alveoli and pulmonary capillaries (stimulated by increases in pulmonary interstitial and capillary pressure).

Corollary Discharge to Sensory Cortex

Additionally, there is evidence that corollary signals or efferent copies of brainstem respiratory center motor output, i.e. similar parallel outputs, are also transmitted to higher brain centers in the sensory cortex and may play an important role in the perception of dyspnea. This creates a conscious awareness of the outgoing respiratory motor output to the ventilatory muscles.[3] So far, specific receptors and pathways for this parallel relay have not been identified. However, rostral projections from brainstem respiratory motor neurons to the midbrain and thalamus have recently been described in the cat.[4] Studies have shown that in conditions, such as decreasing muscle length, muscle fatigue or respiratory muscle weakness, where a greater motor command is required to achieve a given tension in the muscle, there is an increased appreciation or perception of respiratory effort.[5,6] Further, the perception of the respiratory effort increases with increase in central respiratory motor output and is proportional to the ratio of the pressures generated by the respiratory muscles to the maximum pressure-generating capacity of those muscles.[7]

Chest Wall Receptors

There is evidence that afferent signals from mechanoreceptors in the joints, tendons, and muscles of the chest may play a role in modulating respiratory sensations. In a study using evoked-potential techniques to determine whether low-threshold muscle afferents from the chest wall project to cortical levels in conscious human subjects, evidence for a short-latency projection was provided.[8] It has been suggested that an uncomfortable sensation of breathlessness may be induced by muscle spindles in the intercostal muscles being activated out-of-phase with the respiratory cycle.[9] On the other hand, in-phase chest wall vibration (inspiratory intercostal muscles vibrated during inspiration and expiratory intercostal muscles vibrated during expiration) has been shown to decrease pathologic dyspnea in patients with chronic respiratory disease at rest and on exercise.[10-12]

Dyspnea increases with the level of respiratory chemical drive during hypercapnia, but intensity of the sensation was found to be greater when the consequent increase in ventilation was constrained. Voluntary hypoventilation produces an intense sensation of breathlessness even when blood gases are maintained constant that correlates closely with the degree to which the tidal volume is reduced.[13] In conscious patients on mechanical ventilator receiving the low levels of ventilation, dyspnea may be troublesome requiring heavy sedation.

Lung Receptors

Studies have shown that vagal influences, independent of ventilatory and blood gas changes may modulate the sensation of dyspnea. Mechanically ventilated patients with high cervical spinal cord transaction who are thus unable to transmit impulses from chest wall receptors experience a sensation of air hunger when their ventilation is reduced.[14,15] Further, vagal blockade or vagotomy has been shown to reduce dyspnea during exercise, breath-holding and after pulmonary venous obstruction.[16-18]

The three types of sensory receptors in the lungs that have been considered as the site of origin of dyspnea are: (i) the bronchial C-fiber receptors (ii) the pulmonary stretch receptors, i.e. the Slowly Adapting (SARs) and Rapidly Adapting Receptors (RARs), (iii) and the Juxtapulmonary (J) receptors, also referred to as pulmonary C-fiber receptors.

The bronchial C-fiber receptors were first described by Coleridge and Coleridge.[19] These are located mainly in the wall of the large airways, both extrapulmonary and intrapulmonary, and are characteristically accessible to chemicals injected only into the bronchial circulation. Their exact anatomical location in the airway wall or in relation to the capillaries of the bronchial circulation is not known. While their natural stimulus is as yet unknown, it is hypothesized that these are likely to contribute to bronchoconstriction and mucous secretion as the chemicals that they are sensitive to, include various inflammatory mediators.[20] That they do not contribute to an acceleration of respiration was shown by Anand[21] in cats where an impressive activity produced in them by injecting phenylbiguanide into the bronchial circulation was accompanied by an inhibitory influence on respiration. Capsaicin, on the other hand injected by a similar route is accompanied by a marked stimulation of respiration that persists after bilateral vagotomy thereby showing that the increase in respiration did not originate by their stimulation.

Located in the mucosa and smooth muscle of the extrapulmonary and intrapulmonary airways, the slowly and rapidly adapting pulmonary stretch receptors sense lung volume and are stimulated by lung inflation, and the latter, also by lung deflation.[22] These conduct their impulses in myelinated vagal afferents. According to Widdicombe[23,24], who changed their name briefly to "irritant receptors" because these receptors could trigger cough and reactions to noxious agents, and as also reviewed recently by Ravi and Kappagoda,[25] the stimulation of RARs produces dyspnea. However, in man, a rapid voluntary hyperventilation, which would produce a high-frequency neural discharge in RARs does not give rise to dyspnea or to any kind of unpleasant sensations.[26-28] Further, these receptors produce relief from dyspnea or breathlessness under circumstances when they would be maximally stimulated.[29] After breath-holding at total lung capacity, there is immediate relief with rapid expiration, i.e. a physiological stimulus for maximizing neural output from RARs.[30] This relief is similar to the relief felt on breathing in, after holding the breath at functional residual capacity that would be attributed to the stimulation of the SARs.[29] There are no correlative studies available between humans and mammalian species on RARs and their likely role in generating dyspnea are an extrapolation of findings from the latter. So far, no human studies of dyspnegenic effects of RAR activation have been carried out. Their role in producing dyspnea on exercise is not clear. However, there is evidence in animals that RARs play a role in the respiratory responses in acute pulmonary congestion due to heart failure. Activation of RARs causes a reflex increase in respiratory rate, tracheal tone and mucus secretion in the airways. A rise in left atrial pressure (LAP) by 5 mm Hg in dogs, which is sufficient to stimulate RARs[31] may occur on exercise. This is not accompanied by dyspnea. However, sustained application of LAP of 10 mm Hg for 15 minutes produces a sustained activation of RARs along with some activity in bronchial C fibers and very little in pulmonary C fibers. At this level, the increase in extravascular compartment in the lung is largely in the proximal airways. Thus, it has been suggested that the RARs may come into play in the early stages of acute heart failure.[25] Pulmonary edema requires an elevation of LAP to 20 mm Hg. At this level, RARs, bronchial C fibers and pulmonary C fibers, all show strong activation and are likely to modulate respiratory responses in frank pulmonary edema. Interestingly, the response of the RARs to pulmonary congestion is nonadapting unlike the response to maintained inflation where rapid adaptation occurs.

The J capillary receptors, or type J-receptors, so named because they lie in close proximity to the pulmonary capillaries in the interstitium of the lung, were discovered by Paintal.[33] These are stimulated in animals by pulmonary congestion and by intravenously injected chemicals to give rise reflexly to tachypnea.[32-36] These are also called pulmonary C-fiber receptors. Majority (80%) of these are non-myelinated C-fiber endings and 20% are A-delta fiber endings. Their natural stimulus is an increase in pulmonary blood flow leading to a rise in Pulmonary Capillary Pressure (PCP). Doubling of pulmonary blood flow (i.e. doubling cardiac output), which will result in increasing the PCP, increases their activity from nearly zero to 0.7 impulses/sec,[35] a stimulation which in earlier studies has been shown to stimulate respiration.[33,34] A correlative study of animals and human subjects demonstrated that small doses of lobeline i.v. (10–15 μg/kg) gave rise to respiratory reflexes and distinct sensations in the throat or upper chest by stimulation of J (pulmonary C fiber) receptors.[36] The sensations felt on J-receptor stimulation resemble those reported in dyspnea,[36-40] including those perceived by patients in left ventricular failure,[40] patients of mitral stenosis on exercise,[39] and those reported by subjects with high altitude pulmonary edema[28], suggesting a common origin of these. Thus, dyspneic sensations are produced under conditions in which the J (pulmonary C fiber) receptors are stimulated, and, conversely no or reduced dyspnea is observed under circumstances when they are not being stimulated or their stimulation is reduced. Valvulotomy relieves dyspnea in mitral stenosis[39] even without changes in skeletal muscle peak exercise oxygen consumption[41] muscle structure or biochemistry[42] and lung-function abnormalities,[43] suggesting that J-receptors are involved in the sensation of breathlessness on exercise in these patients as surgery relieves pulmonary congestion. Paintal[26-28] has provided evidence that an increase in interstitial fluid volume resulting from elevated pulmonary arterial and capillary pressures contributes to the breathless sensation after moderate and severe exercise. In acute heart failure, their activation follows that of RARs.[25] That vagal afferents are involved in the origin of the sensation of dyspnea, is strongly supported by the observation that intravenous lobeline does not produce sensations described above in patients who have undergone bilateral lung transplantation.[44]

Chemoreceptors

Changes in arterial blood gases, hypoxia with/without hypercapnia, are commonly observed in respiratory conditions causing dyspnea and are sensed by central and peripheral chemoreceptors. Their contribution to the sensation of dyspnea becomes difficult to evaluate as changes in lung and chest wall mechanics are associated with, and usually precede the alterations in blood gases in the pathophysiology of these conditions. However, certain models and interventions allow the evaluation of dyspnea due to chemically-induced increases in respiratory motor activity, independent of changes in chest wall and lung mechanics. Both ventilator-dependent quadriplegics with high cervical spinal cord transection and normal subjects paralyzed with neuromuscular blocking agents experience the sensations of air hunger when $PaCO_2$ is increased.[45,46] Moreover, hypercapnia produces greater dyspnea than exercise and voluntary hyperventilation at similar levels of ventilation.[47] In normal subjects paralyzed with a neuromuscular blocker and receiving adequate mechanical ventilation, acute hypercapnia and hypoxia cause respiratory distress. Importantly, the changes in dyspnea ratings precede changes in ventilation.[48] It has also been shown that the administration of oxygen during exercise produces a small reduction in ventilation, but a larger and consistent decrease in dyspnea suggesting that hypoxemia itself may be a stimulus for dyspnea independent of ventilatory changes.[49]

PATHOPHYSIOLOGICAL MECHANISMS OF DYSPNEA

Dyspnea may be produced by diseases and disorders affecting the respiratory centre, the ventilatory apparatus, including the airways and the lung parenchyma, gas exchange and oxygenation, and cardiopulmonary hemodynamics. As the activity of the respiratory centre, the ventilatory response in the terms of changes in lung volumes, pressures and airflows, changes in blood gas tensions and alterations of cardiopulmonary hemodynamics in physiological states and diseases are integrated and influence each other. Dyspnea is likely to be precipitated and modulated by multiple factors and mechanisms in different diseases and disorders of the cardiorespiratory systems. It is also likely that dyspnea experienced by patients represents more than one sensation. The choice of phrases used by patients with a variety of conditions causing dyspnea are distinctly different.[50,51] The pathophysiological mechanisms that operate in the common causes of dyspnea are discussed in the following sections.

In obstructive airways diseases, such as COPD and asthma, the functional abnormalities that may underlie the origin of dyspnea include (Table 10.1):

- Increased work of breathing due to increased resistive loading and functional weakness of the ventilatory muscles.
- Hypoxia and hypercapnia leading to chemoreceptor activation.
- Restriction of lung expansion in a hyperinflated chest and functional abnormalities in lung mechanics worsening on exertion (dynamic hyperinflation).
- Airway inflammation altering vagal afferent activity.
- Afferent signals from mechanoreceptors in the joints, tendons and muscles of the chest.
- Altered pulmonary circulation hemodynamics
- Associated cardiac dysfunction
- Any combination of the above.

In Interstitial Lung Diseases (ILDs), the following abnormalities may contribute to dyspnea (Table 10.2):

- Increased work of breathing due to increased elastic loading and functional weakness of the ventilatory muscles
- Physical restriction of thoracic expansion and functional abnormalities in lung mechanics
- Hypoxia leading to chemoreceptor activation
- Lung interstitial inflammation and fluid changes altering vagal afferent activity
- Afferent signals from mechanoreceptors in the joints, tendons and muscles of the chest
- Altered pulmonary circulation hemodynamics
- Associated cardiac dysfunction
- Any combination of the above.

With such diverse pathophysiological alterations, clearly a single mechanism or pathway cannot explain the origin of the sensation of dyspnea at rest and on exercise in these conditions.

Among the several proposed mechanisms, a popular theory that has been put forth is that dyspnea results from a disassociation or a mismatch between central respiratory motor output and incoming afferent information from the receptors in the airways, lungs and chest wall structures, i.e. the motor response is sensed as being “not matched” with the afferent inputs. The afferent feedback from the peripheral sensory receptors informs the center that the mechanical response of the lungs and chest wall (changes in volumes, pressures and airflows) are not appropriate for outgoing motor output (tension of the inspiratory muscles) leading to the sensation of dyspnea. In simple terms, the ventilatory response of the lungs and the chest wall is inappropriate for the effort. This is the crux of Campbell and Howell hypothesis of "length-tension inappropriateness."[52-54] and is also termed as "neuro-mechanical"[55] or "efferent-reafferent dissociation."[46] In terms of this hypothesis, if the inspiratory muscles contract less than usual for the tension generated because of a noncompliant chest wall, or if the airflow generated is less than expected for a given inspiratory effort or if the volume of inspiration is less than expected for the degree of activation of the muscles, the intensity of respiratory discomfort gets intensified. This dissociation between the efferent and afferent information may occur in patients with a resistive (obstructive diseases) or elastic (restrictive diseases) mechanical load on the respiratory system, or respiratory muscle abnormalities. This mechanism may explain dyspnea associated with breath-holding, increased airways resistance, decreased lung and chest wall compliance, voluntary hypoventilation, as well as that experienced by patients on mechanical ventilation with small tidal volumes and low inspiratory flow rates. However, as discussed above, quadriplegics and normal subjects paralyzed with neuromuscular blocking agents also experience air hunger to a hypercapnic or hypoxaemic stimulus and dyspnea precedes changes in ventilation.[13-15,45-47] The hypothesis also does not explain the dyspnea occurring due to changes in pulmonary hemodynamics on exertion in pulmonary and cardiac diseases.

In the absence of a single hypothesis that integrates all mechanisms of dyspnea, it is convenient to discuss origin of dyspnea in the terms of major pathophysiological alterations that occur in different diseases.

Increased Ventilatory Demand and Activity

Increased output from the brain is the primary manifestation of dyspnea in which the respiratory center may play a role in certain disorders and conditions. While it is possible to voluntarily increase ventilation, it is subjectively not an unpleasant sensation. Patients with psychiatric morbidity may hyperventilate and the corollary discharge from the respiratory center to cortical areas may also bring the increased ventilatory drive to consciousness. The dyspnea commonly seen in the first trimester of pregnancy is likely due to the stimulatory effect of progesterone on the respiratory center in the medulla. However, in most of the diseases causing dyspnea, the increased output of the respiratory center is a response to the increased ventilatory requirements sensed and communicated by the afferent inputs to the center through the neural mechanisms discussed above, rather than a primary abnormality. Abnormalities in gas exchange along with the stimulation of pulmonary receptors, as evidenced by the hyperventilation seen in patients with asthma and pulmonary embolism, may contribute to heightened activity in the center. Patients with a non-compliant wall, increased airway resistance, weakened muscles, or thickened pleura have problems with the ventilatory pump in achieving normal ventilation and derangements of the gas exchange occurring in several diseases leading to hypoxemia, with or without hypercapnia, have increased ventilatory drive to meet the increased ventilatory demand.

The intensity of dyspnea increases progressively with increase in the workload during exercise. However, halving the intensity and doubling the duration of activity reduces the maximal intensity of dyspnea to less than a third.[56,57] This is likely to be due to the increase in respiratory motor output to meet the increased ventilatory demand and a corresponding increase in the sense of effort. The cortex also takes into account the context in which the ventilation has increased in its interpretation. Increased ventilation at rest is likely to cause more dyspnea compared to an activity that gives rise to similar levels of ventilation. This is because higher ventilation at rest is seen as excessive or out-of-proportion to normal requirements at rest while it is considered as more appropriate for the activity. This has been reported in COPD.[58]

Diseases of airways (COPD), lung parenchyma (ILDs) and pulmonary vasculature (pulmonary embolism) that increase dead space and other conditions causing wasted ventilation due to V/Q mismatch require an increase in the minute ventilation to achieve normal gas exchange. Hypoxemia at high altitude and in patients with respiratory disease, stimulates arterial chemoreceptors and increases respiratory motor activity. The increased ventilatory demand leads to an increased motor command under these conditions, contributing to dyspnea.

Another stimulus for excessive ventilation is a consequence of deconditioning because of prolonged inactivity imposed by cardiorespiratory diseases. Patients with COPD have an early and accelerated rise in blood lactate production by skeletal muscles during exercise and the consequent metabolic acidosis is an additional respiratory stimulus leading to excessive increase in the ventilation for a given level of exercise, and this increases dyspnea.[59] This would limit exercise capacity leading to a vicious cycle of greater inactivity and consequent deconditioning and greater dyspnea.

While the level of ventilation often correlates well with the intensity of dyspnea, increased motor output is unlikely to be solely responsible for dyspnea. Even with conditions causing increased ventilation, the subjective sensations experienced by subjects are different. As pointed out above, at similar level of ventilation, hypercapnia produces greater dyspnea than voluntary hyperventilation and exercise[47] and the relief in dyspnea with exercise in hypoxic subjects afforded by supplemental oxygen is out of proportion to the reduction in ventilation.[49] Increased ventilatory drive is unlikely to produce an uncomfortable awareness of breathing as long as the response of the chest wall and lungs is commensurate with the requirements and the effort expended in ventilation is sensed as "normal." This requires a normal lung mechanics and an efficient musculature. However, when the other alterations as discussed in the following sections occur, the increased ventilatory drive becomes the driving factor for dyspnea.

Mechanical Inefficiency of Ventilatory Pump

A weakness or mechanical inefficiency of the respiratory muscles results in a mismatch between the central respiratory motor output and achieved ventilation. Some conditions that predispose to ventilatory failure increase the work of breathing due to altered lung mechanics (COPD, asthma, ILDs, obesity, kyphoscoliosis), whereas others cause severe respiratory muscle weakness. Specific reasons for muscle weakness include critical illness (electrolyte imbalance, acidosis, shock, severe sepsis), chronic illness (poor nutrition, cachexia), and neuromuscular diseases and dysfunction (steroid myopathy). In order to generate the inspiratory pressures required to initiate inspiration, greater effort is required by the inefficient muscles and even then, the maximal inspiratory pressures may be decreased.[60] Thus, there is an increased gap in the pressures achieved and pressures required leading to an inefficient ventilatory pump and dyspnea progressively worsens.[61]

The abnormalities of lung mechanics at rest and on exercise have been studied extensively in COPD.[62] Besides a partially reversible airflow limitation, COPD is characterized by a redistribution of lung volumes at rest and on exercise. The airflow limitation results in a requirement of a longer expiratory time to exhale a given volume of air. Associated emphysema leads to a loss of elastic recoil and hence the driving pressure for expiratory airflow, causing further reduction in flow rates along with an increased size of the alveoli and larger volume to be exhaled. The increased airflow limitation (resistance) and loss of elastic recoil (reduced compliance) lead to reduced time constants of the lung units and this impedes emptying within the available expiratory time. The result is an incomplete emptying and hyperinflation at the end of expiration (increased end-expiratory lung volume, EELV). As the next inspiration begins before the previous expiration has been completed, the airways pressures are still positive relative to the atmosphere (auto PEEP). This increases the inspiratory threshold, i.e. inspiration can begin only after this pressure is overcome. The increased inspiratory threshold thus increases the work of breathing and is also the cause of inspiratory dyspnea. On exercise, the increase in ventilation further increases the volume to be exhaled while the increase in respiratory frequency further reduces the expiratory time resulting in a progressive increase in the EELV due to the stacking of incomplete expirations and worsening of dyspnea. This phenomenon is called "dynamic hyperinflation" and occurs on even mild exertion in patients with severe COPD. The hyperinflation also causes breathing to take place on the stiffer upper portion of the pressure-volume curve, resulting in an added elastic load that further increases the inspiratory threshold load. The hyperinflation also imposes a "restriction" on the extent to which the tidal volume can be increased on exercise thus compromising ventilation. The increased resistive and elastic loads lead to increased work of breathing. Further, the low and flattened diaphragm is an inefficient muscle of inspiration. Finally, inspiratory muscle shortening with hyperinflation reduces the mechanical efficiency. In the face of the added resistive and elastic loads and mechanical disadvantages of a hyperinflated chest, to achieve a given level of ventilation requires substantial additional effort and if the ventilatory pump is able to achieve the required level of ventilation, it does so at the cost of increased work of breathing and if it is not, respiratory failure occurs. Either way, a mismatch is sensed between the respiratory drive and the achieved ventilation.

Evidence for the above concepts has been provided. On exercise, patients with mild COPD were found to have higher dyspnea ratings for a given work rate and ventilation compared to normal subjects. Changes in EELV were greater and dyspnea intensity increased as inspiratory reserve volume decreased, indicating dynamic hyperinflation. Thus, dyspnea in COPD arises out of the combined deleterious effects of higher ventilatory demand and abnormal dynamic ventilatory mechanics.[63] Bronchodilators may relieve dyspnea partly by reducing hyperinflation and restoring the lungs and the chest wall to a more mechanically advantaged position. It has been shown that more patients with COPD respond to bronchodilators by increasing the forced vital capacity, reflecting a reduced residual volume, than by an increase in expiratory flow rates and the forced expiratory volume in the first second(FEV_1).[64] An increase in the inspiratory capacity following bronchodilators also captures the same effect.[65] This is a "pharmacological lung volume reduction." The beneficial effects of lung volume reduction surgery are also attributable to reduced volumes of the chest wall and restoration of the muscle length to a more favorable and efficient position. Reduction in hyperinflation due to the prolongation of expiration favoring lung emptying is also the likely mechanism by which breathing exercises, such as pursed lip breathing, that form part of pulmonary rehabilitation programs, reduce dyspnea and improve exercise capacity.[66] The strategy of smaller tidal volumes and slower frequency with greater inspiratory-to-expiratory time ratios during mechanical ventilation of these patients also has the same physiological basis.

Changes in lung mechanics in acute exacerbations of asthma are similar with the important difference that these are largely reversible. However, asthmatic airways that have undergone substantial remodeling have a largely irreversible airway narrowing, thus increasing the work of breathing persistently and suffer from the same consequences of hyperinflation as outlined above in patients with COPD.

In ILDs, inspiratory pressures are increased due to lower lung compliance, which also reduces the tidal volume. The increased work of breathing is related to the increased elastic load, the resistive load being largely normal or low. The demand for increased ventilation is met by increasing the respiratory rate particularly during exertion. Thus, such patients typically have a rapid and shallow breathing. Reduced tidal volume also increases the proportion of wasted ventilation due to increased dead space/alveolar vthe center. This drives ventilation further in order to have sufficient alveolar ventilation. Tachypnea reduces expiratory time more than the inspiratory time, thus increasing the inspiratory duty cycle. The result is an increased ventilatory effort in ILD. Again, as in patients with COPD, this requires an adequately responsive ventilatory apparatus that may achieve the required ventilation, but at the cost of increased work of breathing and if it cannot, respiratory failure will follow.

Thus, in both, COPD and ILDs, the level of central respiratory motor output required to achieve the desired ventilation increases. Given the functional abnormalities in lung mechanics in these diseases discussed above, the mechanical response of the lungs is achieved at the cost of increased effort of breathing that is likely sensed as uncomfortable. In both diseases, dyspnea intensity is increased at any given ventilation compared with age-matched healthy individuals.[67] Addition of external resistive and elastic loads leads to a progressive rise in the intensity of dyspnea as the applied load increases.[68]

Harty et al.[69] applied external thoracic restriction in healthy subjects and observed that during exercise, this produced a shallow and rapid breathing pattern and was associated with greater dyspnea, with descriptors of dyspnea used by subjects (inspiratory difficulty, tightness and increased effort) similar to those reported by ILD patients. A contribution of pulmonary and chest wall mechanoreceptors in the sensation of dyspnea was suggested. O'Donnell et al.[70,71] using a combination of external chest wall restriction and added dead space in normal subjects to create a closer approximation of the physiologic disturbances caused by ILD, and, on direct studies in patients with ILD has provided evidence that the inability to expand tidal volume appropriately in the face of an increased drive to breathe contributes to the intensity and quality of dyspnea in ILD.

As the natural history of COPD and most interstitial and diffuse parenchymal lung diseases is one of progressively worsening pathology and hence the load on breathing, progressively increasing dyspnea on exertion is the classical presentation of both the types of diseases.

While the above mechanisms operating in COPD and ILDs may support Campbell and Howarth's hypothesis of "length-tension inappropriateness"[52-54] or neuro-mechanical dissociation, it is also difficult to prove because comprehensive measurements of efferent and afferent signals are not currently possible. Further, the pathophysiology in these states that may be responsible for dyspnea extends beyond the alterations in lung mechanics (Tables 10.1 and 10.2). There are associated changes in cardiopulmonary hemodynamics on exertion along with alterations in arterial blood gases. These are sensed independent of the changes in ventilation by different pathways as described above. Thus, other mechanisms are likely to operate as well.

Afferent Pulmonary Vagal Receptors Stimulation

As discussed above, sensory receptors in the lungs are innervated by the vagus nerves and consist of three types: Pulmonary stretch receptors (SARs and RARs) and bronchial C-fiber endings in the large airways, and pulmonary C-fibers (type J-receptors).[72] While the irritant receptors appear to modify the intensity of dyspnea associated with induced bronchoconstriction,[73] and the airway stretch receptors appear to modify breathlessness

TABLE 10.1: Mechanisms of dyspnea in chronic obstructive pulmonary disease

Increased ventilatory demand
- Increased ventilation/perfusion inequality
- Increased physiological dead space
- Hypoxemia and hypercapnia
- Early lactic acidosis due to muscle deconditioning

Inefficient ventilatory pump
- Altered lung mechanics (increased airway resistance, hyperinflation, including dynamic, leading to increased resistive and elastic loads)
- Poor nutrition
- Muscle fatigue due to the sustained increased work of breathing, mechanical disadvantage and systemic inflammation

Stimulation of vagal afferents
- Airway Inflammation
- Increased pulmonary blood flow and congestion on exercise

Signals from mechanoreceptors in the joints, tendons and muscles of the chest

Coexistent cardiac failure (diastolic/systolic)

Psychiatric morbidity

TABLE 10.2: Mechanisms of dyspnea in interstitial lung diseases

Increased ventilatory demand
- Increased ventilation/perfusion inequality
- Increased physiological dead space
- Hypoxemia and hypercapnia (later stages)
- Early lactic acidosis due to muscle deconditioning

Inefficient ventilatory pump
- Altered lung mechanics (deflation and decreased lung compliance leading to increased elastic load)
- Poor nutrition
- Muscle fatigue due to sustained increase in work of breathing

Stimulation of vagal afferents
- Interstitial inflammation and edema
- Increased pulmonary blood flow and congestion on exercise

Signals from mechanoreceptors in the joints, tendons, and muscles of the chest

Coexistent cardiac failure (diastolic/systolic)

Psychiatric morbidity

by altering ventilatory pattern, neither of these receptors has been shown to be specifically dyspnegenic. On the other hand, in addition to being short of breath, the sensations felt by the subjects on the stimulation of type J-receptors were found similar to the manifestation of dyspnea[36-40] and also resemble the cluster of "breathlessness-indicating sensations" of left ventricular failure patients,[39] as well as those felt by the patients of high altitude pulmonary edema.[28]

In two recent investigations, a significant similarity was found between the nature of respiratory sensations evoked in response to intravenous lobeline and modest treadmill exercise in cardiac disease patients,[38] and with a six-minute walk in mitral stenosis patients.[39] The latter were found to have an increase in the dose of lobeline required to produce the threshold levels of respiratory sensations after valvulotomy reduced the pulmonary wedge pressure, thus suggesting a reduction in the intensity of the natural stimulus, i.e. pulmonary congestion. This was accompanied by an increase in the symptom-free six-minute walk distance further substantiating their role in subserving the sensation of dyspnea on the exertion and limitation of exercise. This mechanism of relief is supported by the fact that neither the skeletal muscle peak exercise oxygen consumption[41] nor muscle structure or biochemistry change[42] and lung-function abnormalities still persist.[43] The evidence points to a major role for the J-receptors in the origin of dyspnea in acute heart failure.

However, acute increases in extravascular fluid volume in the airways also activate the RARs and with larger increases, both the RAR and the C-fiber receptors in the airways and the alveoli are activated. Activation of RAR causes a reflex increase in respiratory rate, tracheal tone and mucus secretion in the airways. It has also been suggested that the RARs play a significant role mediating the respiratory reflexes associated with acute heart failure.[25] However, direct evidence in humans is lacking.

Thus, whereas the role of vagal afferents in the genesis of the sensation of dyspnea in acute heart failure is fairly well established, there is uncertainness on their contribution to dyspnea in COPD and ILDs. The level of exercise that can precipitate dyspnea in these conditions is much less than that required to alter cardiopulmonary hemodynamics and produce stimulation of these afferents and exercise limitation in normal subjects. However, these may play a facilitator role as pulmonary blood flow does increase on exercise and in addition, coexistent cardiac failure is common in these conditions. Further, inflammatory changes in the airways and the interstitium may lower the thresholds for their stimulation, as discussed later. The stimulation of J-receptors on experimental aortic occlusion in cats was more closely related to the fall in lung compliance than the increase in pulmonary artery pressure associated with congestion.[74] Interestingly, the rapid shallow breathing that is characteristic of ILDs resembles the reflex response to the stimulation of pulmonary J-receptors. Therefore, J-receptors may be responsible for the dyspnea related to interstitial edema. Direct observations on the role of J-receptors in ILDs are however limited and do not support the suggestion that vagal stimulation is the principle mechanism for dyspnea on exercise in ILD.[75]

Inflammation is the most prominent pathological feature of both COPD (and asthma) and ILDs. The responses of lung receptors may be altered in these conditions and may be different from those observed in normal animals, as well as human volunteers. Recent studies have revealed that the sensitivity of bronchopulmonary C-fibers can be markedly elevated in acute and chronic airway inflammatory diseases, probably caused by a sensitizing effect of certain endogenously released inflammatory mediators. Normal physiological actions, such as an increase in tidal volume (e.g. during mild exercise) can then activate these C-fiber afferents, and consequently may contribute, in part, to unpleasant breathing efforts in diseases with inflammation in the airways and parenchyma.[76] Inhaled PGE_2 is known to stimulate vagal afferent receptors in the lung in particular C-fiber endings, without a significant increase in airway resistance. It significantly increases the magnitude of the dyspneic sensation when compared with inhaled saline at the same levels of workload, ventilation, and oxygen consumption on exercise and thus may modulate receptor responsiveness by lowering the thresholds for stimulation.[77] Only a small percentage (< 10%) of the bronchopulmonary C-fibers exhibit CO_2 sensitivity under control conditions, but alveolar hypercapnia exerts a consistent and pronounced stimulatory effect on the C-fiber endings during airway inflammation produced by acute exposure to ozone, infusion of inflammatory mediators, such as adenosine or prostaglandin E_2 and airway exposure to poly-L-lysine, a cationic protein known to induce mucosal injury.[78] Several other autacoids (e.g. bradykinin, neurotrophic factors, certain lipoxygenase metabolites, etc.) can also sensitize pulmonary C-fibers. These mediators may also contribute to the heightened respiratory discomfort found in patients with airway inflammatory diseases.[79]

Increases in pulmonary arterial and capillary pressures occur due to pulmonary vasoconstriction in healthy individuals exposed to the hypoxic environment at high altitude. Dry cough and choking sensations felt in the throat and upper chest of subjects with high altitude pulmonary edema are likely caused by the activation of pulmonary C-fibers and the same may also be the mechanism for similar respiratory sensations that occur after moderate or severe exercise at sea level.[80]

More evidence for the involvement of vagal afferents in the sensation of dyspnea has been obtained in studies employing local nerve blocks with anesthetic agents in normal subjects, as well as observations in patients who underwent vagotomy for some indications. Exercise studies in a patient who developed severe exertional dyspnea after a failed surgery that resulted in unilateral pulmonary venous obstruction demonstrated a markedly abnormal ventilatory pattern consistent with excess vagal stimuli to the respiratory center. Temporary and then permanent vagal interruption markedly altered the respiratory pattern and improved her functional status.[18] In normal human subjects, bilateral local anesthetic block of the vagus nerves at the base of the skull was found to diminish breath-holding sensation, and prolong breathholding.[17] On the other hand, results of vagotomy in patients have been inconsistent in relieving dyspnea, although the pattern of breathing may be altered with deeper breathing.[16, 81] In normal subjects, alveolar deposition of lignocaine to block unmyelinated pulmonary afferent nerves did not reduce dyspnea on exercise.[82] However, anesthesia of central airways in normal subjects was shown to produce slower and deeper breathing and reduced breathlessness on exercise.[83] In contrast, in patients with interstitial lung disease, anesthesia of the central airways did not modify the perception of dyspnea.[75] Intravenous adenosine in normal subjects does not cause bronchospasm, yet causes dyspnea, most likely by an effect on vagal C-fibers in the lungs.[84] The same effect was also seen in asthmatics.[85]

Blood-gas Abnormalities

Blood-gas abnormalities occur frequently in acute emergencies in several respiratory diseases and also develop in due course in the natural history of several progressive chronic diseases, including COPD and ILDs. Intuitively, one may expect these to contribute to the sensation of dyspnea. However, these correlate poorly with the magnitude of dyspnea in individual patients. As both hypoxaemia and hypercapnia also increase the central respiratory motor output acting through peripheral and central chemoreceptors,[86] the increased ventilation confounds any independent effect these may have on the respiratory sensations. Increased ventilation is not necessarily "unpleasant" and therefore, the contribution of changes in blood gas abnormalities to the origin of the sensation of dyspnea is difficult to evaluate.

However, dyspnea is aggravated by hypercapnia at the similar levels of ventilation on exercise and voluntary hyperventilation suggesting a direct effect on the intensity of dyspnea.[47] The effect of $PaCO_2$ on ventilation is effected through changes in hydrogen ion concentration at the medullary chemoreceptors. While this may operate during acutely developing hypercapnia, in patients with chronic hypercapnia, metabolic compensation neutralizes changes in hydrogen ion concentration and consequently limits ventilatory responses and changes in respiratory sensation. Acute changes in hydrogen ion concentration may explain the dyspnea of diabetic ketoacidosis and renal insufficiency.

Yet, a complementary role of hypoxaemia in the sensation of dyspnea cannot be denied. Certainly, the administration of oxygen reduces dyspnea in both acute and chronic respiratory failure, even in the absence of any changes in ventilation.[49] Bye et al.[87] noted that exercise duration was increased with the addition of supplemental oxygen in patients with ILD. It also clearly lowered ventilation measured at a given time-point during exercise. Marciniuk et al.[88] observed that in patients with ILD, exercise was limited primarily by dyspnea in some and by leg fatigue in others. The former had greater ventilation and demonstrated the evidence of expiratory flow limitation during exercise. However, the average arterial oxygen saturation at peak exercise was equal in both groups. This suggests that hypoxia may not be the primary mechanism causing dyspnea in ILDs. Moreover, relief in dyspnea on oxygen therapy may result from other beneficial effects, including improved ventilatory and peripheral skeletal muscle performance, as well as improved cardiac performance. It may also modify central processing of other stimuli causing dyspnea and thus influence respiratory sensation. It is also like to have a strong psychological effect, as it is synonymous with life.

Psychological Origins of Dyspnea

Considering the inherent element of perception and the subjective nature of the sensation of dyspnea, psychological factors undoubtedly play an important role in its origin. Not only factors related to personality are important as the major determinants of perception, psychiatric morbidity complicates chronic disabling diseases and thus confounds the symptoms. The communications between cortical areas concerned with the perception of dyspnea and the respiratory control center are two-way pathways. Interpretation of incoming corollary discharge to the cortical centers as being “unpleasant” is modulated by psychological, behavioral and cultural factors. However, emotional upsets may themselves lead to an increase in ventilation and a worsening of dyspnea. This is classically observed in hyperventilation states, such as acute anxiety and also contributes to dyspnea in acute exacerbations of asthma, COPD and other acute emergencies.

Associations were found between respiratory symptoms, including dyspnea and psychological scales incorporating anxiety, anger, depression, and cognitive disturbance with the perception of respiratory symptoms increasing with a rise in psychological scores.[89] The prevalence of anxiety and depression among patients with COPD is significantly higher than that in the general population and has been linked to increased mortality, decreased functional status and decreased quality of life.[90] Sarcoidosis is associated with a high rate of psychiatric comorbidity, including major depressive disorders and may contribute to a poorer quality of life.[91] A more fundamental association between psychiatric morbidity and respiratory illness has also been proposed, suggesting that a subset of patients may be more prone to develop both. In anxiety states, such as panic disorders, the respiratory abnormality most often reported is increased CO_2 sensitivity.[92]

Psychiatric morbidity and respiratory diseases may be involved in a vicious cycle, the former leading to a greater perception of symptoms of the latter, and, the latter giving rise to the former as a complication. A psychotherapeutic approach, managing both may thus be more associated with improved outcomes.[93]

SUMMARY

Dyspnea is a complex symptom of several diseases and disorders of the respiratory, cardiovascular and other systems. The subjective and complex nature of the symptoms of dyspnea makes it difficult to develop an appropriate model to study its origin. All such models have limitations and hence there are large gaps in the state of knowledge about its underlying mechanisms. It is unlikely that a common mechanism and pathway may explain its genesis. The origin of dyspnea is likely to be multifactorial, and, qualitative and quantitative differences exist in the perceived sensation of breathlessness in these different conditions. Increased central ventilatory drive, inefficient ventilatory pump, stimulation of vagal afferents by inflammatory and cardiopulmonary hemodynamic changes, as well as alterations in lung mechanics, sensations from mechanoreceptors in joints, tendons and muscles of the thorax, abnormalities of arterial blood gases, and acid-base balance acting through peripheral and central chemoreceptors, and psychological factors are the multiple factors involved. Management of patients based on an understanding of the pathophysiological mechanisms of dyspnea will be more rewarding both for the patient and the physician.

Surfactant

Gyanendra Agrawal, SK Jindal

INTRODUCTION

Pulmonary surfactant is a complex mixture of phospholipids and proteins that reduce surface tension at the air-liquid interface of the alveolus, thus preventing its collapse during end-exhalation. This chapter outlines the complexity of the surfactant system and describes its basic biophysics, physiology and biochemistry. The physiological basis for the pathology and the treatment of salient respiratory diseases due to altered surfactant metabolism in children and adults, are also reviewed briefly.

COMPOSITION OF LUNG SURFACTANT

Lung surfactant is produced by type II alveolar epithelial cells, also called pneumocytes and consists of a mixture of phospholipids (PLs) and proteins.[1] Lung surfactant recovered from Bronchoalveolar Lavage (BAL) fluid, is composed of approximately 80 to 85% PLs, mainly Dipalmitoylphosphatidylcholine (DPPC), 5% to 10% proteins, and 5% to 10% other lipids[2] (Table 11.1).

Phospholipid Composition

Phospholipids are the main components that confer surfactant its ability to lower surface tension. The most abundant form of alveolar phospholipid is the tubular myelin, which are large relatively dense aggregates (termed large aggregate surfactant) composed of phospholipids and surfactant proteins. Small less dense particles (small aggregates) are also present in the alveolar space, which represent the remnants or catabolic forms of surfactant. These are taken up, reutilized or catabolized by type II pneumocytes or alveolar macrophages.

TABLE 11.1: Composition of lung surfactant[3]

Phospholipids	**80%–85%**
Phosphatidylcholine (PC)	75% (50% DPPC)
Phosphatidylglycerol (PG)	12%
Others	
Proteins	**5%–10%**
SP-A	50%–70%
SP-B, SP-C and SP-D	30%–50%
Neutral lipids	**5%–10%**
Cholesterol	90%–95%

DPPC, dipalmitoyl-PC

Lung surfactant contains several major PL classes: Phosphatidylcholine (PC), Phosphatidylglycerol (PG), Phosphatidylethanolamine (PE), Phosphatidylinositol (PI), Phosphatidylserine (PS), Sphingomyelin (SPM) and Lysophospholipid (LPL) (Table 11.1). Dipalmitoyl-PC accounts for at least 50% of PC molecular species, which is a critically important component for achieving the maximum reduction of surface tension. Surfactant is secreted into the amniotic fluid, levels of certain PLs like total PL, DPPC and lecithin to sphingomyelin ratio are used to predict the pulmonary maturity prior to the birth of preterm infants. Phosphatidylethanolamine, phosphatidylserine and lysophosphatidylcholine are present in relatively low concentrations in lung surfactant, an increase in concentration can indicate ongoing inflammation and cellular injury.[2]

Protein Components

Four surfactant proteins, called SP-A, SP-B, SP-C and SP-D, named in the order of discovery, are unique to the lung and intimately associated with surfactant lipids, each playing specific roles in surfactant homeostasis or host defense. Two classes of proteins have been distinguished on the basis of their structures. The small hydrophobic surfactant proteins B and C enhance the spreading, adsorption and stability of surfactant lipids required for the reduction of surface tension in the alveolus. They are essential for lung function and pulmonary homeostasis after birth, and are important protein components of the animal-derived surfactant replacement preparations used for the treatment of infantile respiratory distress syndrome. The two collectins, SP-A and SP-D, are relatively abundant hydrophilic proteins. They contribute to innate immunity and perhaps to the extracellular trafficking of pulmonary surfactant rather than to its surface activity.

Surfactant protein-A (SP-A): SP-A is the major surfactant protein in regard to relative abundance in the surfactant complex. It is a 26 to 38 kDa oligomeric glycoprotein that is expressed by the Clara cells and alveolar type II cells of the distal respiratory epithelium. The deduced primary structure and amino terminal sequencing of rat SP-A reveal five discrete structural domains: (1) Amino terminal domain (Asn^{1}-Ala^{7}); (2) Collagen-like sequence of Gly-X-Y repeats (Gly^{8}-Pro^{80}); (3) Hydrophobic neck region (Gly^{78}-Val^{114}); (4) Carbohydrate recognition Domain (CRD) (Gly^{115}-Phe^{228}), especially Mannose Binding Protein (MBP); and (5) Two differentially occupied consensus sites for asparagine-linked glycosylation.[4] SP-A is composed of a series of discrete structural domains. Monomers of SP-A form trimers by triple-helix formation in the collagen-like domains. The fully assembled molecule is an octadecamer, stabilized by intertrimeric and intratrimeric disulfide bonds at the amino terminus. The human SP-A gene locus consists of two functional genes, SP-A1 and SP-A2, which have four coding exons located on the long arm of human chromosome 10.

Deletion of the SP-A gene in mice does not alter survival or lung function after birth. However, they are highly susceptible to lung infection by bacterial, viral and fungal pathogens, indicating the primary role of SP-A in innate host defense of the lung. SP-A has been shown to bind to the lipid A moiety of endotoxin and to a variety of pulmonary pathogens, including *Haemophilus influenza* type A, *Streptococcus pneumoniae*, *Mycobacterium tuberculosis*, *Pneumocystis jiroveci* and influenza A virus. SP-A also binds to alveolar macrophages and stimulates chemotaxis and phagocytosis.[4] SP-A also function as an alveolar opsonin to defend hosts without specific antibody or for immediate protection against remotely encountered pathogens that require the clonal expansion of lymphocytes for adequate response. It also acts an anti-inflammatory agent by inhibiting certain cytokines like interleukin-1 and TNF-α. SP-A increases the association of lipids with type II cells, but does not appear to increase the internalization of lipid.

The expression of SP-A in amniotic fluid increases in late gestation, and is a marker for determining fetal lung maturity. The levels of SP-A in BAL fluid are elevated in many diseases like sarcoidosis,[5] hypersensitivity pneumonitis,[5] idiopathic pulmonary fibrosis,[6] alveolar proteinosis[7] and asbestosis.[8] Thus, elevated SP-A levels in BAL fluids are not specific or diagnostic of a specific disease, however, may reflect acute alveolar inflammation.

Surfactant protein-B (SP-B): SP-B is a relatively small, 79 amino acid, amphipathic peptide produced by type II epithelial cells lining the alveoli. It is encoded by a single gene located on chromosome 2, which is expressed in the lung by type II cells and Clara cells. SP-B is tightly associated with surfactant PLs, and forms tubular myelin in the presence of SP-A, phospholipids and calcium. It is then secreted into the alveoli, where it interacts at the surface of surfactant lipids, forming stable monolayers and bilayers that reduce surface tension. The dimeric structure of SP-B may account for its ability to cross-link different lipid membranes. It plays a critical role in surfactant homeostasis by promoting the adsorption of lipid molecules into the expanding surface film by a factor of >150;[2] and enhancing their stability during the compression and expansion that occur during the respiratory cycle. This effect is further accelerated by the presence of calcium ions such that mixtures of phospholipids and SP-B display almost the same biophysical properties as the whole lung surfactant.

SP-B is critical for lamellar body formation and its deficiency results in the abnormal processing of SP-C due to abnormal lamellar body formation. Its transcription is regulated by TTF-1.[9] The concentration of SP-B increases with advancing gestation, as does SP-A. SP-B is absolutely essential for breathing and SP-B(-/-) mice, and infants with mutations in SP-B gene die of respiratory distress after birth.[10] SP-B reconstitutes most of the surface activity of natural lung surfactant, in combination with lipids. The sequence region 64–79 of SP-B contains peptides with two or more basic residues that include arginine or lysine. This sequence has been shown to be most effective in lowering surface tension.[11]

Surfactant protein-C (SP-C): SP-C is the only surfactant protein, which is expressed exclusively by type II cells in the mature lung. The human gene is found on chromosome 8 and SP-C, too, is translated as a larger preprotein and processed intracellularly. SP-C precursor protein is routed with SP-B precursor protein to multivesicular bodies, where both are processed and packaged into lamellar bodies for secretion into the air space along with phospholipids. Insertion of the surfactant protein-C peptide into phospholipid membranes disrupts the packing of lipids, thereby enhancing the movement of lipid molecules between the sheets of membrane and vesicles. The main function of SP-C is to maintain the biophysical surface activity of the lipids. This occurs through an acceleration of the rate of adsorption at the air-water interface, as well as through an increase in the resistance of surfactant to inhibition by serum proteins or by edema fluid. SP-C stabilizes the surface activity of the surfactant film during the expansion and compression involved in breathing.

Its transcription is regulated by TTF-1. SP-C(-/-) Swiss black mice does not demonstrate abnormalities in lung structure at birth.[12] In a congenic 129/Sv strain, SP-C deficient mice developed severe, progressive pulmonary disease associated with emphysema, alpha-smooth muscle actin staining, monocytic infiltrates, and epithelial cell dysplasia in conducting and peripheral airways.[13] SP-C is also an active component of various mammalian surfactant preparations that are used to treat respiratory distress syndrome in preterm infants.

Surfactant protein-D (SP-D): SP-D is the second hydrophilic surfactant protein and also a collectin. The molecular weight of the SP-D monomer is approximately 43 kDa that is structurally similar to SP-A and other C-type lectins. The collagenous domain of SP-D is much larger than that of SP-A, is attached directly, without a connecting region to the CRD domain. About 12 SP-D monomers are present in the lungs, three of which join to form trimers. These four trimers form a crisscross-like structure that may bind to bacterial Lipopolysaccharide (LPS) and to cell surfaces, forming larger networks of cells or bacteria. The interaction of SP-D microbial pathogens is Ca^{++} and carbohydrate dependent. SP-D is produced in type II cells and in Clara cells, the gene being located on long arm of chromosome 10. The SP-D gene consists of 8 exons spanning >11 kb of DNA. The majority (70%) of SP-D is found dissolved in the watery surfactant residue, whereas SP-A, SP-B and SP-C are almost entirely found in an association with lipids. Levels of SP-D and SP-A are potential markers for lung maturation because the studies of amniotic fluid and lung tissue have demonstrated the increasing levels of SP-D with increasing gestational age.

For SP-D, there are no known functions that are related to the biophysical activity of surfactant. The molecule may be of great importance for the nonadaptive defense system of the lung. SP-D has specific binding sites on alveolar macrophages,[14] can induce a "respiratory burst," and stimulates their phagocytotic activity. SP-D also binds to polymorphonuclear granulocytes, LPS, *Escherichia coli*, *Pseudomonas aeruginosa*, Influenza A virus and *P. jiroveci*.[2]

Other Lipids

Surfactant contains a small percentage of neutral lipids that are generally comprised of cholesterol, cholesterol esters, diglycerides, triglycerides and free fatty acids (FA). The roles of these components for surfactant function have not been fully characterized.

FUNCTIONS OF LUNG SURFACTANT (TABLE 11.2)

The best documented function of surfactant is its ability to reduce surface tension. Surface tension arises from the difference between the attractive forces on molecules at an air-liquid interface. As a result of this, there is a force or tension in the surface film that resists expansion of the bubble and consequently acts to contract surface area. This force is surface tension and has a value of 70 mN/m or 70 dynes/cm of water at 37°C.[9] The amphipathic

TABLE 11.2: Functions of lung surfactant

Biophysical Functions

1. Reduces surface tension and prevents collapse of alveoli during expiration
2. Increases lung compliance and decreases work of breathing
3. Maintains gas exchange area of lung
4. Counteracts edema formation by balancing hydrostatic filtration forces
5. Improves mucociliary clearance
6. Reduces bronchoconstriction
7. Smooth muscle relaxant

Host Defense Functions

1. Opsonization of bacteria, viruses, fungi and allergens
2. Facilitate phagocytosis of pathogens
3. Modulate production of inflammatory mediators
4. Direct microbicidal activity
5. Promote phagocytosis of apoptotic cells

properties of lung surfactant allow its alignment at the air-liquid interface. Surfactant intermolecular repulsive forces act by opposing attractive forces between molecules at the liquid surface. The presence of lung surfactant in the alveoli, therefore, reduces surface tension preventing collapse of alveoli. Natural surfactant generally lowers surface tension to < 6 dynes/cm.[15]

The law of LaPlace states that the pressure difference (ΔP) across a spherical surface (e.g. alveoli) depends on the ratio between surface tension (σ) and the radius (r) of the sphere.[1,2]

$$\Delta P = \frac{2\sigma}{r}$$

A constant surface tension in conjunction with a small radius would lead to a high pressure difference across the sphere. So, there is an increased tendency for the collapse of smaller alveoli during expiration. The lowering of surface tension by the lung surfactant allows pressure differences across the alveolus to remain constant throughout the respiratory cycle; and thus, preventing collapse of alveoli and small airways. The surfactant also increases lung compliance, and reduces the work of breathing. It counteracts edema formation by balancing hydrostatic forces. Surfactant forms a nonspecific barrier against the adhesion and invasion of microorganisms into the lung.[16] Furthermore, airway surfactant was shown to improve mucociliary clearance,[17] and to reduce bronchoconstriction in response to inhaled allergens.[16] A recent study suggested the role of surfactant as a smooth muscle relaxant.[18]

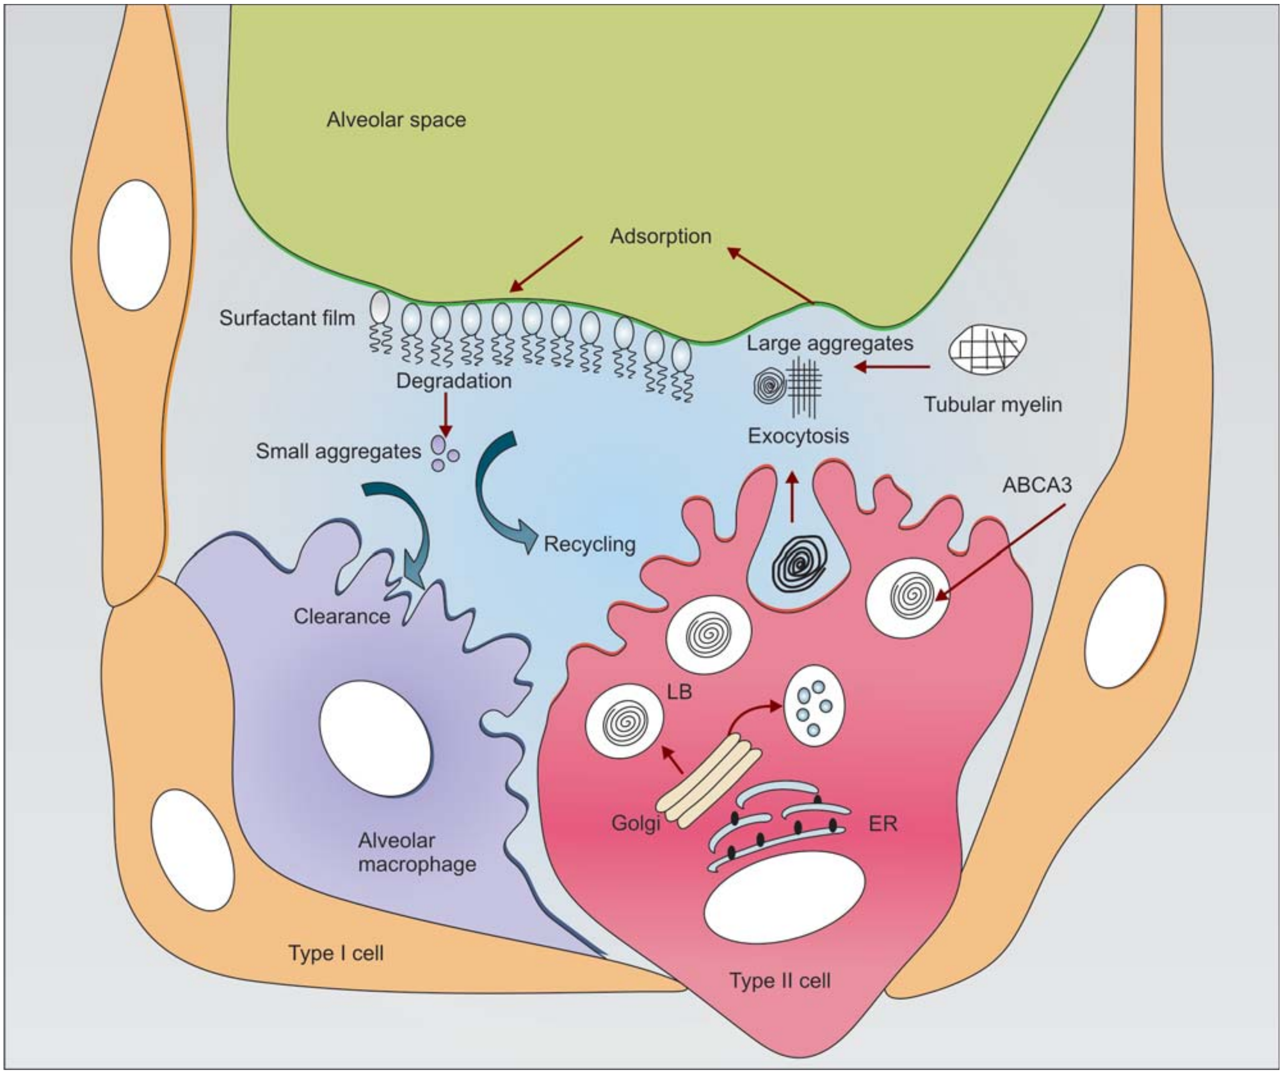
Host defense functions of surfactant are primarily assured by SP-A and SP-D. Nevertheless, surfactant PLs also influences pulmonary immune function. SP-A and SP-D facilitate phagocytosis of pathogens by at least three different mechanisms: Opsonization of pathogens, ligand-activation of immune cells and upregulation of cell receptors involved in microbial recognition.[19] Collectins also have a direct microbicidal activity against bacteria or fungi without the presence of immune effector cells.[19,20] The mechanisms leading to microbial killing have not been fully characterized. SP-A and SP-D promote the uptake of apoptotic cells by alveolar macrophages.[21] It also slow the release of proinflammatory mediators and inhibit the activation of nuclear factor-κB and the L-selectin-induced signal transduction.[22] The phospholipid components in large abundance under normal conditions have been shown to suppress various lymphocyte and macrophage immune function. They suppress the proliferation, immunoglobulin production and cytotoxicity of lymphocytes; and also inhibit endotoxin-stimulated cytokine (TNF, IL-1, and IL-6) release from macrophages.[2]

SURFACTANT METABOLISM AND SURFACTANT FILM FORMATION (FIG. 11.1)

The size of the surfactant pool is tightly regulated by mechanisms controlling the synthesis, recycling and catabolism of surfactant.[23] Both during development and postnatally, the synthesis of pulmonary surfactant is subjected to precise regulatory controls. It increases markedly in late gestation and is enhanced by a variety of hormones, including the glucocorticoids. In fact, glucocorticoids are routinely used to induce lung maturity in infants at risk for preterm delivery. Thyroxine accelerates type II cell differentiation while acting synergistically with glucocorticoids to enhance the distensibility of the lung and DPPC synthesis. Beta-agonists and purines, such as adenosine triphosphate are also potent stimulators of surfactant secretion. Mechanical stretches, such as lung distension and hyperventilation have also been found to be involved in stimulating surfactant secretion. Certain cytokines like Tumor Necrosis Factor alpha (TNF-α) and Transforming Growth Factor Beta (TGF-β) and insulin inhibit surfactant production depending on experimental conditions.

Surfactant PLs and proteins are synthesized in the endoplasmic reticulum of type II alveolar cells. In addition, SP-A, SP-B and SP-D are produced by Clara cells and submucosal cells. PLs and surfactant proteins are processed through the Golgi apparatus and packaged into lamellar bodies (intracellular storage organelles). ABCA3 is present in the limiting membrane of the lamellar bodies, where it is likely to regulate lipid transport at the air-liquid interface. Surfactant is exocytosed from these structures into the alveolar hypophase (a liquid layer between air and lung epithelium) where it exists in the form of heterogeneous PL-rich aggregates, including tubular myelin. Tubular myelin is the most abundant form of alveolar phospholipid and consists of large dense aggregates. 'Large aggregates' have been demonstrated to have a strong ability to lower surface tension (highly active surface) and to contain the hydrophobic surfactant proteins along with SP-A and specialized PL structures (i.e. lamellar bodies and tubular myelin). Phospholipids from extracellular surfactant structures form continuous monolayers and multilayers of phospholipids that line the alveolar spaces and airways, with their polar heads oriented toward the liquid and their acyl chains toward the air.

During breathing the surfactant film at the air-liquid interface is subjected to "compression" and "expansion." The following concept has been proposed for surfactant film behavior: At the end of expiration, the surfactant



Alveolar space
Adsorption
Surfactant film

film is enriched in DPPC as the phospholipids with unsaturated fatty acid chains are squeezed out of the surfactant film (compression). DPPC films can be tightly compressed, which allows the achievement of very low-surface tensions at the end of expiration and thus prevents alveolar collapse. Although the ability to maximally lower surface tension is attributable to the presence of DPPC in surfactant films, proper surfactant function, which is highly dynamic *in vivo*, could not be achieved without the action of other lipids and surfactant proteins. The surfactant components, which are expelled during expiration, are reincorporated into the surface-active film during inspiration (expansion). This leads to enhanced surfactant spreading. PLs with unsaturated or shorter FA chains introduce fluidity into surfactant films, and allow fast surfactant adsorption and respreading at the air-liquid interface. Anionic PLs (PG and PI) enhance surfactant film adsorption and film stabilization during the respiratory cycle.[24] Surfactant proteins (SP-B, SP-C and SP-A) are essential for the packaging of surfactant PL in lamellar bodies, organization of tubular myelin, and ultimately formation of an efficient surfactant film at the air-liquid interface.

Normally, surfactant is inactivated by mechanical and biologic processes and converted into small, surface-inactive aggregates. "Small aggregates" typically represent surfactant, which is being removed from the air-liquid interface for recycling, or has been injured during inflammation. Approximately, 70 to 80% of the "small aggregates" are taken up by alveolar type II cells, transported to phagolysosomes, and reused or catabolized. Alveolar macrophages internalize and catabolize the remaining surfactant pool, a process critically dependent on GM-CSF.[25] Although less than 10% to 15% of surfactant is cleared by catabolism by the alveolar macrophages, this pathway is critical in controlling steady state surfactant concentrations *in vivo*. GM-CSF acts within the lung by stimulating the terminal differentiation of alveolar macrophages, principally by raising the levels of transcription factor PU.1.[7] It has been shown in experimental studies that GM-CSF(-/-) and GM-CSF receptor-deficient mice are not capable of clearing surfactant proteins and phospholipids, causing alveolar proteinosis.[26] GM-CSF signaling also enhances the function of peroxisome-proliferator–activated receptor γ (PPARγ), another transcription factor that regulates many cellular functions, including intracellular lipid metabolism.[26] These findings explain how inhibiting the binding of GM-CSF to its receptor causes the decreased clearance of surfactant from the alveolar spaces.

DISORDERS OF SURFACTANT METABOLISM

Surfactant alterations have been implicated in the pathophysiology of a number of alveolar and airway diseases. This occurs either due to decreased production or due to accelerated breakdown by oxidation, proteolytic degradation, inhibition or inherited defects of surfactant metabolism (Table 11.3). Decreased clearance of surfactant by alveolar cells, causing the excess deposition of surfactant in the lungs can also cause respiratory failure. Surfactant alterations have been described in a much larger number of respiratory diseases (Table 11.4).[2] It is beyond the scope of this chapter to address all of these. Some of the important diseases linked to the altered surfactant metabolism have been briefly discussed as under.

TABLE 11.3: Mechanisms of lung surfactant abnormalities[3]

- **Deficient surfactant formation (synthesis/storage/release)**
  - Immaturity of type II pneumocytes
  - Injury to type II pneumocytes

    - ARDS
    - Meconium aspiration syndrome
    - Pulmonary hemorrhage
- **Excess surfactant**
    - Alveolar proteinosis

Infantile Respiratory Distress Syndrome

Respiratory Distress Syndrome (RDS) is one of the most common causes of morbidity in preterm neonates, the risk increases as the gestational age decreases. The preterm infant who has RDS has low amount of surfactant that contains a lower percent of disaturated phosphatidylcholine species, less phosphatidylglycerol, and less of all the surfactant proteins than surfactant from a mature lung. Minimal surface tensions are also higher for surfactant from preterm than term infants. Decreased alveolar surfactant activity associated with pulmonary immaturity causes atelectasis, alveolar collapse and hypoxemia. Radiological findings include a diffuse reticulogranular "ground glass" appearance (resulting from alveolar atelectasis) with superimposed air bronchograms. Oxygen support and mechanical ventilation are typically required.

Surfactant Replacement Therapy (SRT) significantly reduces the incidence, severity and mortality associated with RDS, and it has become the standard of care in the management of preterm infants with RDS.[27] SRT reduces the incidence of death, air leak syndromes and intraventricular hemorrhage in premature infants. Surfactant treatments are effective because of complex metabolic interactions between surfactant and the preterm lung. The large treatment dose functions as substrate; it is taken up by the preterm lung and is reprocessed and secreted with improved function. The components of the treatment surfactant remain in the preterm lung for days. If lung injury is avoided, then surfactant inhibition is minimized.[27] Prenatal corticosteroids complement surfactant to further enhance lung function.

Exogenous surfactant preparations, both natural and synthetic, are approved for the treatment and prevention of RDS in infants. Synthetic surfactants differ most notably from natural surfactants in their protein composition. Surfactant preparations containing surfactant proteins B and C act rapidly, increasing lung volumes and compliance, and thereby decreasing the requirements for positive pressure ventilation and oxygen supplementation. Synthetic surfactant preparations lacking surfactant proteins, e.g. colfosceril palmitate, improve lung functions in a delayed manner. However, the overall efficacy of both the type of preparations does not differ much, and are now the standard treatment for RDS. Prophylactic SRT in patients who are at risk for RDS, particularly those infants born at <30 weeks gestation, improves neonatal survival and reduces morbidity. For infants in whom RDS develop, SRT early in the course of RDS, before surfactant inactivation plays a prominent role in lung pathophysiology, is superior to later SRT when lung disease is more advanced.[28]

Inherited Defects of Surfactant Metabolism

A variety of inherited defects of surfactant metabolism includes:

Hereditary SP-B Deficiency

Homozygous SP-B gene (SFTPB) mutations lead to surfactant dysfunction and lethal respiratory distress. Most infants with SP-B deficiency are present with progressive respiratory failure in the first 24 to 48 hours of life. Pulmonary function studies and radiographic findings in these infants are consistent with surfactant deficiency. Radiographic findings include alveolar infiltrates and collapse, reticular-granular infiltrates and air bronchograms in term infants. The disorder is usually inherited as an autosomal recessive condition due to mutation in the SFTPB gene located on chromosome 2. SFTPB mutations are detected in approximately 10% of full-term infants with unexplained respiratory failure.[23] The carrier rate for SFTPB mutation is estimated to be ~1 in 1000.[29] SFTPB mutations include nonsense mutations, point mutations, frameshift mutations, splice-site mutations, deletions and insertions in the SFTPB gene. A single mutation, termed 121 ins 2 (a net insertion of two nucleotides in codon 121 that causes a frame shift, unstable surfactant protein B messenger RNA, and a failure to synthesize surfactant protein B precursor protein), accounts for approximately the two thirds of mutant SFTPB alleles.[23] However, heterozygous relatives of surfactant protein B–deficient infants do not have clinically apparent lung disease.[30]

SP-B deficiency disrupts the formation of lamellar bodies and tubular myelin. The normal packaging and routing of SP-C is also disturbed by SP-B deficiency. Misprocessed surfactant protein C precursor protein (proSP-C) accumulates in amniotic fluid and intracellularly in the airway lumen, causing a proteinosis-like syndrome. Detection of this surfactant protein-C precursor protein fragment in BAL fluid of affected patients, by immunohistochemistry, is useful in the diagnosis of hereditary surfactant protein B deficiency. The definitive diagnosis is made by the identification of both mutations in alleles of the SFTPB gene by nucleotide sequence analysis. The disorder is refractory to surfactant replacement therapy and most infants die within the first month of life, despite maximal medical therapy. The only known treatment is lung transplantation; it has been found that long-term outcomes after lung transplantation for SP-B deficient infants are similar to those of infants transplanted for other indications.[31]

Some other uncommon forms of mutations in SP-B gene that cause partial deficiency of surfactant protein B have been associated with chronic interstitial lung disease in childhood. Most of these children often require intermittent oxygen therapy.

Hereditary SP-C Deficiency

Mutations in the human SP-C gene (SFTPC) resulting in the lack of SP-C represent a rare cause of acute and Chronic Lung Disease (CLD) in infants and adults.[23] SP-C deficiency is inherited as an autosomal dominant disorder; and the mutation could be familial or de novo. This is associated with various forms of interstitial lung disease, including Nonspecific Interstitial Pneumonitis (NSIP), Chronic Pneumonitis of Infancy (CPI), and Idiopathic Pulmonary Fibrosis (IPF); and susceptibility to ARDS following lung injury and infection. Both direct toxicity of abnormal proSP-C, and deficiency of mature SP-C are involved in the pathophysiology of the lung disease caused by SFTPC mutations. Since surfactant protein C may have other functions, including reuptake and catabolism of surfactant particles and surfactant function in the alveolus, it is unclear whether all or some of these activities contribute to the pathogenesis of lung disease caused by mutations in SFTPC.[23] Considerable allelic heterogeneity exists, but there is no obvious correlation between genotype and disease severity. Severe cases resulting in death in early infancy and some requiring lung transplantation have been reported.[9]

ABCA3 Transporter Gene Mutation

Mutations in the ABCA3 transporter gene have been frequently implicated in severe neonatal lung disease and chronic lung disease in older individuals.[32] The genes for ATP-Binding Cassette (ABC) transporters encode membrane proteins involved in the transport of compounds across biologic membranes, and 14 ABC genes have been associated with distinct genetic diseases in humans till now.[33] Mutations in the gene encoding ABCA3 have been found in children with severe neonatal respiratory disease and older children with some forms of interstitial lung disease.[34] ABCA3 mutations are not confined to a single group, and infants from several major racial or ethnic groups can be affected. Generally, this disease presents within first few days of life in full-term infants, with clinical and radiographic features suggestive of surfactant deficiency. Newborn infants are present with grunting, chest retractions and cyanosis followed by rapidly progressive respiratory failure. Diffuse air space consolidation, air bronchograms and reticular–granular infiltrates are seen on chest radiographs.

Most of these patients are refractory to conventional therapies like lung-protective ventilation and ECMO, resulting in respiratory failure and death in the first months of life. Respiratory failure does not respond to the surfactant replacement therapy, and lung transplantation is the only known treatment for this disease. Some infants can also present with persistent pulmonary hypertension of the newborn.[35] Alveolar proteinosis, interstitial thickening, hyperplasia of alveolar type II cells, loss of normal alveolar structure, and features of Desquamating Interstitial Pneumonia (DIP) are certain ultrastructural findings associated with ABCA3 mutations.

ABCA3 gene mutation related lung diseases are inherited in an autosomal recessive manner with phenotypic heterogeneity ranging from fatal to milder forms. Certain forms of Pediatric ILD (pILD) particularly DIP, chronic pneumonitis of infancy, and nonspecific interstitial pneumonitis have been related to the ABCA3 mutations.[34] Some of these children may have a family history of neonatal lung disease. The mechanism for decreased severity of lung disease in these children remains unclear, but it is speculated that it may be related to reduced function rather than complete absence of the ABCA3 protein. It has also been suggested that ABCA3 can be a candidate gene for other pulmonary disorders involving surfactant dysfunction, including the neonatal respiratory distress syndrome and disorders with a later onset such as asthma and the acute respiratory distress syndrome.[32]

Nucleotide sequencing of the gene in infants and children with refractory pulmonary disease may confirm the diagnosis of ABCA3-related lung disease. Nonsense and frameshift mutations, as well as mutations in highly conserved residues and in splice sites of the ABCA3 gene can be identified in the affected group.[32] The E292V mutation in particular is responsible for the genetic etiology of pILD related to abnormal surfactant function.[34] Electron microscopy of lung tissue from affected patients demonstrates the presence of small, atypical lamellar bodies in alveolar type II epithelial cells and the absence of tubular myelin in the airways, indicating an abnormality in intracellular and extracellular lipid homeostasis.

Acute Respiratory Distress Syndrome (ARDS)

ARDS is characterized by sudden onset, impaired gas exchange, decreased static compliance, and by a non-hydrostatic pulmonary edema.[36] Surfactant production decreases due to diffuse lung injury in ARDS, presumably because the alveolar epithelium becomes damaged. Damage to the alveolar Type I cells lead to an influx of protein-rich edema fluid into the alveoli, as well as decreased fluid clearance from the alveolar space. Neutrophils are attracted into the airways by host bacterial and chemotactic factors and express enzymes and cytokines, which further damage the alveolar epithelial cells. Type II epithelial cell injury leads to a decrease in surfactant production, with resultant alveolar collapse. In ARDS, lavage phospholipid, SP-A and SP-B are decreased, and the ratio of small to large aggregates is significantly increased compared with that in non-ARDS patients. Thus, ARDS leads to both deficiency in pulmonary surfactant constituents and inhibition of the activity of the remaining surfactant. This secondary surfactant deficiency may contribute to the disordered mechanical behavior of the lung in ARDS.

Despite the introduction of novel treatments, the mortality from ARDS still remains high. In a single study, the use of surfactant in younger children with ALI was effective in reducing ventilator days and increasing survival.[37] However, most other clinical studies of Surfactant Replacement Therapy (SRT) in adults and children have not shown significant improvement in lung functions; perhaps due to the complex nature of the lung injury in ARDS.[38-40] Therefore, routine SRT for adult patients with ARDS cannot be recommended based on the current data.

Meconium Aspiration Syndrome (MAS)

Meconium aspiration syndrome is also a significant cause of respiratory insufficiency in neonates. When aspirated into fetal lungs, meconium particles mechanically obstruct the small airways. Meconium or the chemical pneumonitis it causes inhibits surfactant function, and inflammation of lung tissue contributes further to small-airway obstruction. Acute intrapulmonary meconium contamination induces a concentration-dependent pulmonary hypertensive response, with 15% to 20% of infants with the meconium aspiration syndrome demonstrating persistent pulmonary hypertension.

Meconium causes surfactant inactivation by multiple mechanisms. It is now known that the fibrillary structure of surfactant is destroyed by the meconium and its surface adsorption rate also decreases.[41] The presence of elevated cell count and proinflammatory cytokines IL-1β, IL-6 and IL-8 as early as in the first six hours suggests that MAS is associated with an inflammatory response. Phospholipase-A_2 (PLA_2) present in meconium, has been found to inhibit the activity of surfactant *in vitro* in a dose-dependent manner, through the competitive displacement of surfactant from the alveolar film. PLA_2 is also known to induce hydrolysis of DPPC, releasing free fatty acids and lyso-PC, which damage the alveolar-capillary membrane and induce intrapulmonary sequestration of neutrophils.[42]

Exogenous surfactant replacement either as bolus therapy or with a diluted surfactant lung lavage have been shown to reverse the hypoxemia and reduce pneumothoraces caused by meconium aspiration, decrease requirement for Extracorporeal Membrane Oxygenation (ECMO), decrease duration of oxygen therapy and mechanical ventilation, and reduce the duration of hospital stays.[43] There is no difference in the different surfactant treatment regimens and it may be related to the heterogeneous nature of this form of lung injury.[44]

Pulmonary Hemorrhage

Pulmonary hemorrhage occurs due to the rise in lung capillary pressure, which could be multifactorial, such as due to the effects of hypoxia, volume overload, congestive heart failure, or trauma induced by mechanical suctioning of the airways. There is a build up of the capillary filtrate in the interstitial space, which can then burst through into the airspaces through the pulmonary epithelium. In addition to the plasma proteins, neutrophils are released, which in turn express proteases, oxygen free-radicals and cytokines. The free oxygen radicals damage type II cells, which decreases surfactant production. Serum albumin, globulin and fibrinogen reduce the rate of adsorption, and increase the minimum surface tension of the surfactant film. The probable mechanism for the increase in surface tension is the competition of plasma proteins with the surfactant, for the interface. Elastase, one of the proteases, damages and degrades SP-A, thereby inhibiting SP-A mediated surfactant lipid aggregation and adsorption *in vitro*.[45] Surfactant replacement therapy may be partially effective in such cases.

Pulmonary Alveolar Proteinosis

Pulmonary Alveolar Proteinosis (PAP) is a rare disorder caused by abundant accumulation of surfactant-derived components in the lungs. The characteristic pathological feature is the filling of alveoli and distal bronchioles with surfactant-derived material that is granular, acidophilic, acellular and amorphous. The substrate stains for periodic acid Schiff and is nearly identical to surfactant. The material consists of approximately 90% lipid (primarily phospholipids), 10% protein, and 1% carbohydrate and is usually sterile.[26] It has been demonstrated that the interruption of GM-CSF signaling in the lung results in pulmonary alveolar proteinosis. (See Chapter 166 for clinical details).

GM-CSF initiated signaling plays unique role in alveolar macrophage function and pulmonary homeostasis, including terminal differentiation and the survival of macrophages, intracellular lipid metabolism, surfactant catabolism and recycling, expression of pathogen receptors, and phagocytosis and killing.[26] Interruption of GM-CSF signaling in the alveolar macrophage either by the absence of the gene encoding GM-CSF or its receptor in mice or, by neutralizing anti-GM-CSF autoantibodies in humans, impairs the catabolism of surfactant by alveolar macrophages. These results in the intracellular build up of membrane-bound concentrically laminated surfactant aggregates. Progressive expansion of the extracellular surfactant pool and accumulation of cellular debris due to the impaired catabolism eventually cause filling of the alveoli, thus reducing the size of the available gas-exchange surface and eventually leading to the clinical syndrome.[7] Current standard of therapy for acquired PAP is whole lung lavage and GM-CSF therapy in selected group of patients.

CONCLUSION

Clinical investigations, research in transgenic mice, and translation of findings from the bench to the bedside have considerably improved our concepts of the pathogenesis and treatment of the diseases linked to the altered surfactant metabolism. Besides, their role in regulating surface activity, the surfactant components may also play in the local immune regulation of the lungs. Except for respiratory distress syndrome in the premature infant, where surfactant deficiency has been unequivocally demonstrated and exogenous surfactant substitution is now part of the routine clinical management, the contribution of surfactant therapy is currently under investigation in a variety of disease states.

Respiratory Defenses and Immunology

Padmavathi Ramaswamy, Padma Srikanth, Vijayalakshmi Thanasekaraan

INTRODUCTION

A moderately active person inhales about 20,000 liters (15 kg) of air every 24 hours, while his food and water consumption for the same period are only about 1.5 kg and 2 kg respectively. Very little selectivity can be exercised over the inhaled materials as compared to the control one has over what is ingested. So, the respiratory tract is constantly exposed to the external ambient environment. The respiratory tract is exposed to environmental toxic substances, such as the smoke, soot, dust and chemicals in the atmosphere, and also to a wide range of organisms such as viruses, bacteria, fungi and parasites. It has been calculated that the average individual inhales about 8 microorganisms per minute or about 10,000 per day. The magnitude of this atmospheric insult on the respiratory tract is much greater in the developing countries. The vulnerability of individuals to these inhaled substances varies widely depending on age, atopic status, nutrition and coexisting conditions. In India, the Acute Lower Respiratory Infection (ALRI) is thought to be responsible for about 490,000 deaths annually, responsible for nearly 1.5% of the entire global burden of disease among children under five years of age.[1] It is, therefore, vital for respiratory clinicians to have a clear understanding of the normal defenses of the respiratory tract.

The defense against foreign material within the lungs is a critical physiological function. This is accomplished by passive mechanisms, such as the branching nature of the respiratory tract and the regulation of airway lining fluid composition. The first line of respiratory defense consists of mechanisms, such as the physical barrier; reflexes, including sneezing and coughing; production of mucus; mucociliary clearance; transport of IgA and antimicrobial mediators (defensins, lysozyme, lactoferrin, lectins). The second-line of defense mechanisms include the innate immunity and the acquired immunity (Table 12.1). These defenses can be overcome by a large number of organisms and inhibitory factors of pathogens, by compromised effectiveness resulting from air pollutants (e.g. cigarette smoke, ozone) or interference with protective mechanisms (e.g. endotracheal intubation or tracheostomy) or genetic defects (e.g. cystic fibrosis). Following exposure to airborne microorganisms (bioaerosols) in air, the defense mechanisms are able to eliminate most of the larger microorganisms; however,

smaller particles and spores may be trapped within the lung tissue, which pose health risks. The impact on health depends on the interaction between genetic differences in the host, agent and environments (duration and exposure dose).

PARTICLE DEPOSITION IN THE RESPIRATORY TRACT

Three regions of respiratory tract have been described based on the deposition of the particles (Fig. 12.1): The nasopharyngeal region or Head Airways Region (HAR) {anterior nares to larynx}, the Trachea-Bronchial Region (TBR) {trachea, ciliated bronchial airways till terminal bronchioles}, and the pulmonary region or Gas Exchange Region (GER) {respiratory bronchioles, alveolar sacs and alveoli}. The particle deposition in HAR is primarily limited to large sized particles that are 10 µm or above. Particles that are 1–10 µm are deposited throughout the respiratory tract, but as the size decreases to 1 µm, these particles can reach the trachea-bronchial region and GER. As the size diminishes below 0.5 µm, the probability of deposition again increases particularly in pulmonary region and to a lesser extent in the trachea-bronchial region.[2,3]

The deposition probability of particles based on the size, in each region can sometimes be used to relate to the anatomical locations of various diseases, e.g. nasal cancer in woodworkers where the airborne particle size is above 10 µm in aerodynamic diameter. The three principal mechanisms for particle deposition are sedimentation, impaction and diffusion. There are several mechanism of clearance, such as dissolution of relatively soluble material with absorption into the systemic circulation, direct passage of particles into the blood, phagocytosis of particles by macrophages, transfer of particle to lymphatic channels and lymph nodes. A proportion of insoluble particles depositing in GER becomes sequestrated either in immotile macrophages or in fixed tissue over a long period of time contributing to cumulative lung burden.

THE DEFENSE MECHANISMS OF CONDUCTING ZONE OF THE AIRWAYS

The upper respiratory tract performs several essential physiological functions, such as filtration, olfaction, phonation, microbial defense and conditioning the air that is inhaled, to maintain a suitable temperature and humidity. The mucosal surfaces of the nasal passages are important for conditioning air before it reaches the more delicate alveolar tissue. Many mucosal glands provide moisture for humidification and mucus to adhere the inhaled dust.

Anatomical Defenses

The anatomy of the upper respiratory tract is composed of many features that help to get rid of particles and pathogens. The inside of the nose is lined with hairs, which filters larger particles that are inhaled. The turbinate bones are covered with mucus that collects particles, which are not filtered by nasal hair. Usually, particles 5–10 μm in diameter are either trapped by nasal hair or adhere to the nasal mucosal surfaces. The anatomy of the upper airway is such that it causes many of the larger airborne particles to impinge on the back of the throat.

Most of the surfaces of the upper respiratory tract are colonized by normal flora. These organisms are regular inhabitants of these surfaces and rarely cause disease. The regular inhabitants of the nose, nasopharynx and oropharynx include *Staphylococcus aureus*, *S. epidermidis* and *nonencapsulated H. influenza.* The normal flora of these areas play a role in maintaining the healthy state of the host by competing with pathogenic organisms for potential attachment sites and often produce substances (toxins or acids), which are bactericidal. There are no resident bacteria in the lower respiratory tract.

Lymphoid Tissue

The adenoids and tonsils are lymphoid organs in the upper respiratory tract that are important in developing an immune response to pathogens and are located in an area where many of these airborne particles are in contact with the mucosal surface. Tonsils consist of localized lymphoid tissue located in the mucosa of the pharynx. Each tonsil consists of an epithelial crypt surrounded by the dense clusters of lymph nodules. At the center of each lymph nodule is a "germinal center" where the lymphocytes proliferate. Pharyngeal tonsils (also called "adenoids") provide sites where immune surveillance cells (lymphocytes) can encounter foreign antigens, which enter the body through inspired air.

The Nasal-Associated Lymphoid Tissue (NALT) consists of the lingual, palatine and nasopharyngeal tonsils, the Waldeyer's ring (Fig. 12.2). Inhaled allergens first encounter the NALT, which is more developed than the bronchus-associated lymphoid tissue. The NALT drains into the cervical lymph nodes. The respiratory tract contains lymph nodes in the mediastinum, hilar areas of the lung and submucosal aggregates present along the airways at branching points. The lymphoid aggregate with a specialized epithelium in the bronchial lamina propria is called Bronchus-Associated Lymphoid Tissue (BALT) (Fig. 12.3), similar to the organized lymphoid tissue of the gut (GALT), e.g. Peyer's patches. The BALT at branching points of the airway is likely to contribute to local immunity. BALT formation following pulmonary infections is coordinated by mediators such as macrophages, dendritic cells, lymphocytes, fibroblasts and endothelial cells.[4] There are dendritic cells present in the airways, which are the antigen-presenting cells that constitutively express a high level of MHC (class II) antigen.[5,6] Dendritic cells become more numerous in response to inhaled antigens and rapidly decrease in number after treatment with glucocorticoids. Dendritic cells after binding with antigens in peripheral airways, migrate via lymphatics to the T-cell-dependant areas of regional lymph nodes, such as BALT and Lung-Associated Lymph Node (LALN), where they encounter naive lymphocytes and initiate a primary immune response. While BALT performs an essential immunologic function such as sustaining the immunity in airways, hyperplasia of this structure may contribute to bronchial pathology. In the overall immune response, BALT plays a minor role.

Mucociliary Clearance Mechanism

The respiratory tract, from the nasal cavity through the bronchi, is lined by ciliated, pseudostratified columnar epithelium with goblet cells. Bronchioles are lined by simple cuboidal epithelium and the lung alveoli are lined by very thin simple squamous epithelium. Pseudostratified respiratory epithelium consists primarily of columnar ciliated cells (Fig. 12.4). Subepithelial cells secrete mucus. The respiratory tract lined with ciliated epithelium is surrounded by thick connective tissue and smooth muscle. Scattered among the ciliated cells are occasional goblet cells. Basal cells are the source of replacement of ciliated and goblet cells.

Respiratory pathogens that reach the respiratory tract are trapped in the mucus layer and are driven upwards by ciliary action (the mucociliary elevator or mucociliary escalator) to the back of the throat.[7] The mucus gel acts as a barrier for bacteria wherein these organisms adhere. The mucus may then be swallowed or coughed out. The sneeze and cough reflexes are important mechanisms for clearing material that accumulates in or irritates the respiratory tract.

i. *Cilia:* The two human lungs contain approximately 0.5 m^2 of ciliated epithelia, with a total number of cilia in the order of 3×10^{12}. Nasal cavity, paranasal sinuses, pharynx, layrnx, trachea are lined by ciliated epithelium. Immediately below the larynx, the tracheobronchial tree is formed by a pseudostratified ciliated columnar epithelium, up to the sixteenth bronchial division of Weibel.[8] The ciliated cells, characterized by their cytoplasmic projections and numerous microvilli, have about 200 cilia.[1] Each cilium has length of 5–7 µm in the trachea and 2–3 µm in the seventh airway generation and a diameter of 0.25–0.33 µm. Cilia beat 600–1,000 times a minute. Cilia are structurally analogous to flagella, where the motion is dependent on the ATPase dynein. As ATP is metabolized, the structural proteins of the cilium change their configuration so that the cilium moves. Cilia move in a characteristic fashion that makes the overlying mucus to move in one direction only towards the pharynx.[9]

ii. *Airway Mucus:* The airway epithelium is covered by a thin layer of Airway Surface Fluid (ASF). The airway surface fluid consists of both a periciliary aqueous layer and an overlying mucus layer. ASF from healthy airways contains approximately 45% Na^+ and Cl^- and 600% more K^+ than plasma. ASF in normal subjects is hypotonic than plasma.[10] The ionic composition of the ASL is assumed to be important for airway function and may be altered in diseases such as cystic fibrosis and exercise-induced asthma.[11] In patients with sustained airway irritation, infection or cystic fibrosis, the ASF composition becomes more isotonic than that of plasma.[12]

The mucus layer is primarily produced by mucus glands in the larger airways and goblet cells in the more peripheral airways. Another type of secretory cell, Clara cell is present in small ciliated bronchioles, which changes to goblet cell in certain disease states.[13,14] Over 125 ml of mucus is secreted each day and forms a continuous sheet like a mucus blanket that covers respiratory tract. The respiratory mucus contains products from several sources, such as the alveolar liquid and secretory products from a variety of cells along the surface of conducting airways. Mucus is composed of $\geq$ 95% of water and approximately 1% of salts and other dialyzable components, 0.5 to 1% free protein and a similar proportion of carbohydrate-rich glycoproteins or mucins.[15] The physical properties of mucus are provided mainly by mucins, which are mucoglycoproteins and proteoglycans secreted from the surface of epithelial cells and from the glands. Phospholipids are also secreted by the epithelial cells and submucosal glands of the airways weakening the adhesion of the mucus and thereby altering its physical properties. Spinability, non-Newtonian viscosity, elasticity, shear thinning (thixotrophy) are some of the rheological properties of the viscoelastic mucus gel of respiratory tract.[16,17] In addition it also possesses properties, such as adhesivity and wettability that determine the capacity of the mucus to protect, hydrate and lubricate the underlying airway epithelium.[18]

Mucus also carries some important bactericidal substances, which contribute to lung defenses such as the secretory IgA, lysozyme, lactoferrin and peroxidases.[19] Lysozyme is a muramidase that degrades a glycosidic linkage of bacterial membrane peptidoglycans. The role of lysozyme as an antibacterial substance is well-known. Besides lysozyme, bronchial secretions contain other antimicrobial substances, such as N-AcetylMuramyl-L-Alanine Amidase (NAMLAA) and β-defensins such as Human Beta Defensins-1 (hBD-1) and hBD-2, and pulmonary lectins and surfactant collections. At a cellular level, lung epithelial cells express S100a, antileucoprotease and large amounts of Major Vault Protein (MVP). In cells infected with *Pseudomonas aeruginosa*, MVP-1 localizes in lipid raft sections of cell membranes and helps to mediate bacterial clearance. The iron binding proteins, such as lactoferrin may reduce the availability of elemental iron that is a cofactor for bacterial replication. However, in addition, lactoferrin may also be bactericidal by binding to endotoxin. The secretory peroxidases (lactoperoxidases) or those from leukocytes (myeloperoxidases) act on thiocyanate ions or produce oxygen radicals, which are bacteriostatic or bactericidal. Epithelial cells are important sources of compounds, such as glutathione that act as antioxidants. They also produce nitric oxide, which has antimicrobial properties. Epithelial cells also actively participate in host defense against inflammation. These cells are capable of producing and responding to a variety of eicosanoids, cytokines and growth factors, which form a complex network regulating inflammatory responses. They also express cell surface receptors that can interact directly with inflammatory cells.

iii. *Mast Cells:* Mast cells store or generate a number of substances, such as histamine, leukotrienes, specific chemotactic factors and proteases, which have potent inflammatory effects. Mast cells are present in mammalian lung in the bronchial wall, in the epithelium itself, and in airway lumen. Evidence implicating mast cells in the induction of airway muscle constriction and mucosal inflammation includes direct studies of mast cell secretion, measurement of histamine release and inhibition of asthmatic reactions with antihistamines and with the inhibitor of mast cell degranulation, sodium cromoglycate. Definitive evaluation of the role of the mast cell in asthma remains unknown, in part because of the general hyperactivity of airway smooth muscle in asthmatics.

iv. *Mucociliary Transport:* Approximately, 90% of inhaled particles with a diameter larger than 2–3 μm are deposited on the mucus overlying the ciliated epithelium. Mucus is propelled by ciliary movement. The particles are transported from the terminal bronchioles to the trachea by the ciliary beats with the mucus. This motion called mucociliary transport occurs at a speed varying between 100 and 300 μm s^{-1}. Mucus acts as a physical and chemical barrier onto which particles and organisms adhere. It is further propelled to the oropharynx where it is either swallowed or expectorated. Cilia start moving from the resting position by bending sideways and backwards. This is called recovery stroke.[20,21] This is followed by an effective stroke during which the cilia move in a plane perpendicular to the cell surface. During this active phase, the tip of the cilia engages in the overlying mucus and sweep it in a cephalic direction. The cilium moves in a layer of periciliary fluid whose depth is a little less than the ciliary length. The overlying mucus is only penetrated by the ciliary tips in the effective stroke and not in the recovery stroke, thereby optimizing the propulsive force of the ciliary beating on mucociliary transport. The thickness of the periciliary layer is critical for effective propulsion of mucus. A wide range of Ciliary Beating Frequencies (CBF) is observed in the central airways.[22] Differences in CBF may be attributed to changes in temperature and humidity. The presence or absence of mucus and the load of mucus may also play a role in determining the CBF. CBF decreases with increasing age.

v. *Factors Affecting Mucociliary Clearance:* Physiological factors such as age, posture, sleep and exercise affect mucociliary clearance. Number of cilia, their structure, activity and coordinated movement are required for normal functioning of the mucociliary clearance.[23,24] Temperature of 37°C and an absolute humidity of 44 mg/dm^3 corresponding to a relative humidity of 100% is required for optimum functioning of cilia. High humidity enhances the functionality of the mucociliary clearance. Mucociliary clearance is also affected by certain risk factors such as malnutrition, exposure to air pollution and smoking. Malnutrition affects the integrity of mucosal epithelial cells. Air pollutants, such as sulfur dioxide, nitrogen dioxide and ozone are known to affect the functioning of the mucociliary mechanism.[25-27] Hair spray exposure is known to depress the tracheal mucous velocity. Cigarette smoke causes excess mucus production, paralyses the cilia and allows mucus to accumulate so that smokers have to cough to clear the secretions. Chronic smoking induces an increased number of abnormal cilia, which causes impairment of tracheobronchial clearance. The ultrastructural ciliary damage seems to be nonreversible, even after a long period of smoking cessation.[28]

Mucociliary clearance is altered in several airway diseases where structural damage to the epithelium or alteration of the mucus composition increases bacterial adhesiveness. Bacterial products, some of which are ciliotoxic may, furthermore, alter the mucociliary clearance. This is true for the *Pseudomonas aeruginosa*-derived elastase.[29] Mucociliary clearance is altered in asthma, chronic bronchitis and cystic fibrosis.[30,31] An abnormal structure of the cilia has been observed in airway diseases, such as chronic bronchitis and in congenital diseases, such as the primary ciliary dyskinesia syndrome ciliary immobility and interciliary discoordination with virtually absent mucociliary clearance. In cystic fibrosis, the most common mutation results in a defective transmembrane receptor protein, which is responsible for mediating cyclic AMP-induced increase in chloride secretion. The resulting alterations in the epithelial overlying fluid composition are believed to lead to poor bacterial clearance.[32]

Cough Clearance Mechanism

Cough is an important defense mechanism. Cough is classically described as a very deep breath, followed by a forced expiration against a closed glottis, which opens suddenly to produce the expulsive phase (Fig. 12.5). This

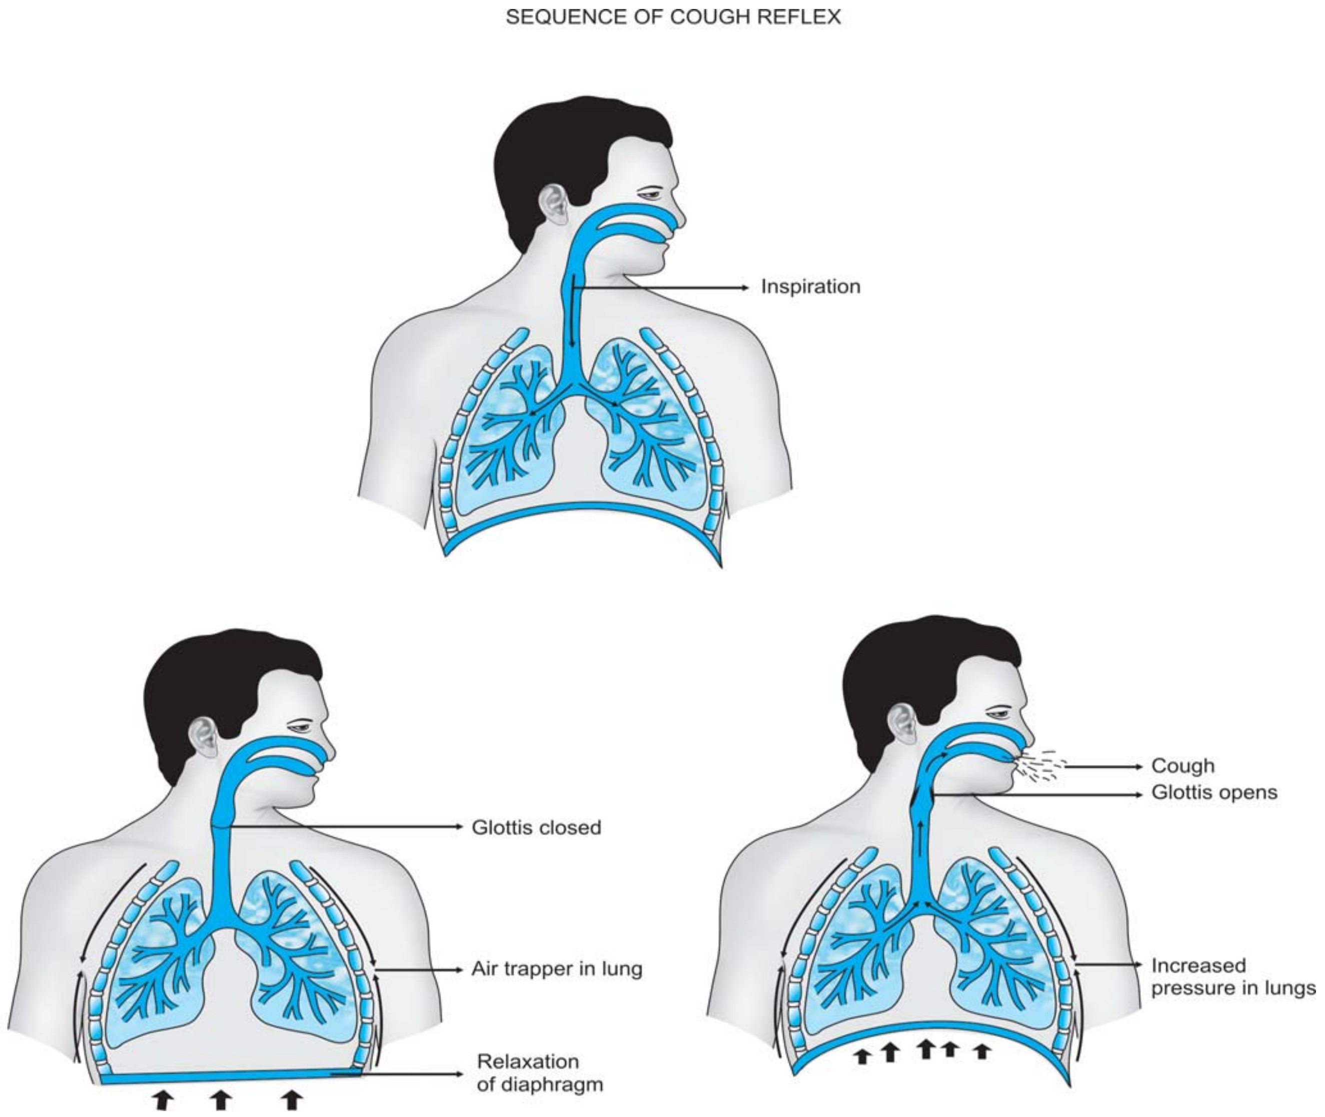

Fig. 12.5: Mechanism of cough reflex

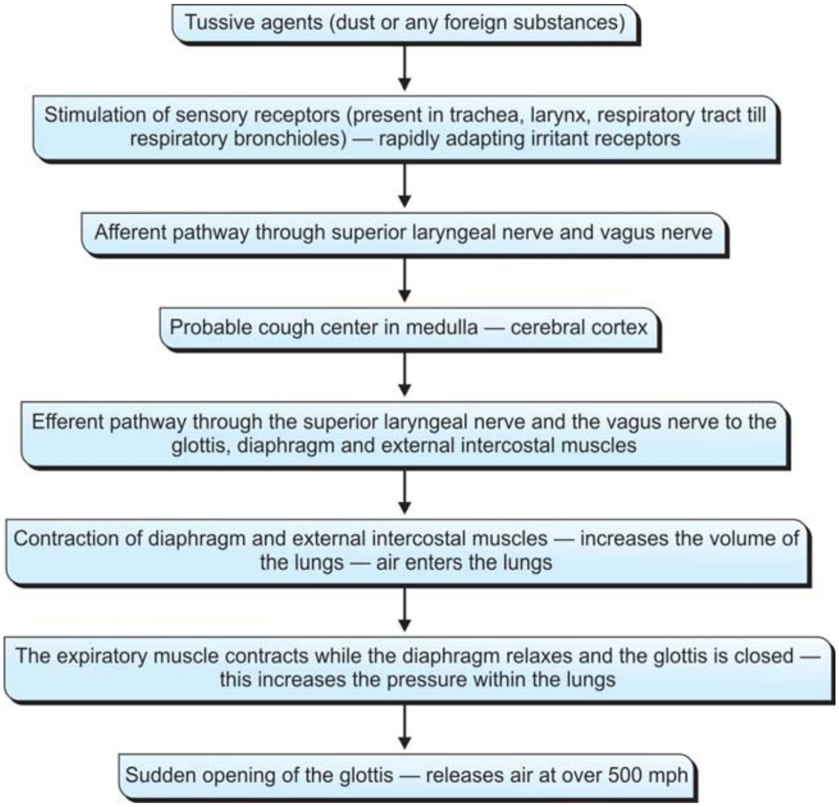
Flow chart 12.1: Mechanism of cough reflex



Tussive agents (dust or any foreign substances)

Stimulation of sensory receptors (present in trachea, larynx, respiratory tract till respiratory bronchioles) — rapidly adapting irritant receptors

Afferent pathway through superior laryngeal nerve and vagus nerve

Probable cough center in medulla — cerebral cortex

Efferent pathway through the superior laryngeal nerve and the vagus nerve to the glottis, diaphragm and external intercostal muscles

Contraction of diaphragm and external intercostal muscles — increases the volume of the lungs — air enters the lungs

The expiratory muscle contracts while the diaphragm relaxes and the glottis is closed — this increases the pressure within the lungs

Sudden opening of the glottis — releases air at over 500 mph

allows enough turbulence and shearing forces in the major bronchi and trachea to extrude material such as debris, infected mucus or products of epithelial damage. The cough is triggered by a very wide variety of stimuli: Mechanical, chemical or inflammatory. It is triggered by irritant receptors in the airways is mediated by the vagus nerve. The cough receptors or rapidly adapting irritant receptors are located mainly on the posterior wall of the trachea, pharynx, at the main carina and at branching points of the large airways. Cough promotes clearance by establishing high shear rates at the epithelial surface. Air forced over the mucosal surface at a sufficiently high velocity, generates lateral force that moves large particles in the direction of air flow. Within certain limits, this process is facilitated by the pliable nature of the walls of peripheral airways. During the forced expiration phase of a cough, the airways are narrowed by the rise in intra-thoracic pressure. The medulla regulates the special breathing pattern that characterizes coughing.

Mechanism of cough reflex is also shown in Flow chart 12.1.

Cough serves as a protective mechanism when mucociliary clearance fails especially in patients with Primary Ciliary Dyskinesia (PCD), also known as immotile ciliary syndrome or Kartagener Syndrome (KS).[13,33] Sneezing is also a protective reflex stimulated when the nasal mucosa is irritated. A series of short inspirations is followed by an explosive expiration, through the mouth, the nose or both. This explosive force carries droplets for long distances, a common means of spreading disease.

THE DEFENSE MECHANISMS OF RESPIRATORY ZONE OF THE AIRWAYS

Most of the respiratory passageways, from the nasal cavity through the bronchi, are lined by ciliated, pseudo-stratified columnar epithelium with goblet cells. Bronchioles are lined by simple cuboidal epithelium and the alveoli by very thin simple squamous epithelium (Fig. 12.6). The squamous epithelial cells of the alveolar walls are sometimes called Type I pneumocytes. This epithelium is exceedingly thin to facilitate diffusion of

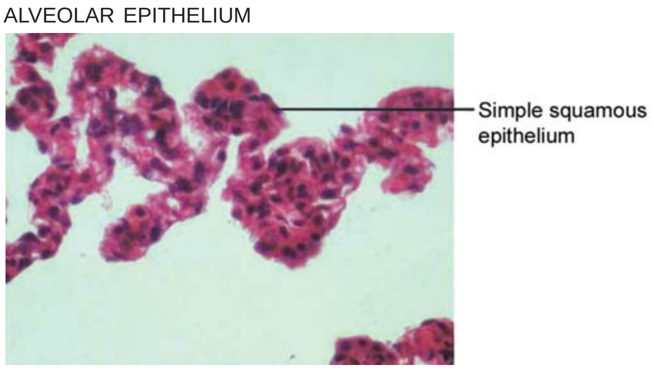


Fig. 12.6: Simple squamous epithelium
(*Courtesy:* Dr Melani Rajendran, Department of Anatomy, SRU)

oxygen and CO_2. The alveolar walls also contain cuboidal surfactant-secreting cells. The surfactant overcomes the tendency of alveolar walls to adhere to one another (which would obliterate the air space). As the epithelium of the respiratory or terminal bronchioles and alveoli are not ciliated, immune effector cells, primarily macrophages, are the dominant mechanism for clearance.

Allergens, toxic particles, microorganisms that have escaped the mucociliary transport system are cleared by the alveolar macrophages by phagocytosis. These alveolar macrophages are sometimes called "dust cells" (Fig. 12.7). Alveolar macrophages provide the defense by phagocytosis, and ingestion of foreign material (Fig. 12.8). Once they have engulfed the material, they may remain in the alveoli, may be cleared along the mucociliary clearance mechanism or may be cleared by lymphatics.[34,35] Alveolar macrophages promote both nonspecific immune responses, such as the production of cytokines (including IL-1, IL-6, tumor necrosis factor, interferon-γ) that mediate an acute-phase response that develops regardless of the inciting microorganism and specific immune response by participating in the production of a variety of antibodies, complex glycoproteins known as immunoglobulins that bind to specific microbial antigenic targets.[36,37] Antibodies can help eradicate the infecting organism by attracting the host's WBCs and activating the complement system. Alveolar macrophages are a phagocyte as well as an effector cell, which initiate immune response. The role of alveolar macrophages in lung immunology is discussed subsequently.

SURFACTANT AND SURFACTANT PROTEIN A (SP-A)

Pulmonary surfactant is a surface-active lipoprotein complex formed by type II pneumocytes. Pulmonary surfactant is critical for maintaining the alveolar stability and gas exchange. Surfactant protein A was the first surfactant protein identified by its association with surfactant lipid. Surfactant protein, B, C and D have also been identified. Surfactant protein A binds to a variety of microorganisms, including viruses, bacteria, mycobacteria, fungi and pneumocystis. Among viruses, SP-A binds influenza, herpes simplex and respiratory syncytial viruses.[38,39] SP-A also binds to and increases phagocytosis of *Streptococcus pneumoniae*, group A *Streptococcus* and *S. aureus*, may bind to peptidoglycan (an important component of the cell wall of gram-positive bacteria). It may not bind to peptidoglycan directly, but inhibits the effect of peptidoglycan by binding to toll like receptor 2.[40] SP-A binds to rough Lipopolysaccharide (LPS), aggregates these gram-negative bacteria and increases phagocytosis, however, it poorly binds to the smooth variants of *Escherichia coli*.[41]

SP-A enhances the adherence and phagocytosis of mycobacteria and fungi, such as *Aspergillus*, by binding the conidia, enhancing their phagocytosis and killing, by human neutrophils and alveolar macrophages.[42] SP-A also binds to and inhibits the growth of mycoplasma, but does not clear the infections, even if it binds to *Pneumocystis jeroveci*.[43]

RESPIRATORY IMMUNE MECHANISMS

The human host is armed with a wide variety of sensors to detect an invading pathogen. The successful clearance of airborne microorganisms follow Pathogen-Associated Molecular Patterns (PAMPs) that bind specific recognition molecules and activate innate immune pathways.

Innate Immunity

The most frequently detected PAMPs in bioaerosols are endotoxins (present in gram-negative bacteria), peptidoglycan (present in gram-positive bacteria) and glucans[44] another PAMP recognition molecule, TLR4 (toll like receptors), allow for endotoxin signaling to be achieved. Microbes that penetrate an epithelial barrier and enter a tissue site encounter three types of sentinel immune cells in the tissues: Tissue macrophages, mast cells and immature dendritic cells. These cells act like guards to differentiate between apoptotic particles generated by normal tissue turnover and particles that are indicative of infection.

The molecules mainly responsible for making this important distinction are those of the family of TLRs.[45] TLR proteins are pattern recognition proteins that obtain their name from the Drosophila Protein Toll with which they share sequence similarity.[46] Although Toll was originally shown to be of importance for dorsal-ventral patterning in fly embryos, generation of adult flies expressing mutant toll revealed that this transmembrane receptor also served as a critical component of host immunity against fungal infection. Toll was shown to be important for host defense against pathogens, because engagement of this receptor induced the production of several antimicrobial peptides (e.g. defensins). Ten distinct mammalian TLRs have been identified and agonists have been identified for some (TLR2, TLR3, TLR4, TLR5, TLR7, TLR8, and TLR9), but not for all of these TLR proteins.

Immune cells develop tolerance to repeated increased expression of TLR4 on the cell surface which leads to inflammatory response to lipopolysaccharide. Respiratory syncytial virus (RSV) present in bioaerosols in domestic day care settings increases TLR-4 expression and sensitizes the respiratory epithelial cells to endotoxin.[47] This may be one of the reasons why secondary bacterial infection occurs following viral infections. A protein called CD14, a mannose receptor specific to LPS and found on surfaces of mature macrophages is present in higher levels in patients with asthma. CD14 levels are also raised in patients exposed to endotoxin. Exposure to endotoxins is associated with increased severity of asthma.

There are a number of cellular receptor families that recognize PAMPs. These PRR families include nucleotide binding and oligomerization domain like receptors (nod like receptors, NLR), C-Type Lectin Like Promoters (CLR) and intracellular receptors to detect double stranded RNA helicase-like receptors. Through various signaling cascades activated TLRs lead to the activation of the nuclear transcription factor, Nuclear Factor Kappa B (NF-κB), this (in turn) leads to the regulation of many host cytokine and cytokine receptor genes, including those for IL-1, Tumor Necrosis Factor-alpha (TNF-α), IL-6, IL-8, IL-10 and IL-12, which have multifactorial effects. Depending on the TLRs activated, cytokine production can result in the full clinical presentation of the acute-phase response, including fever. Whether the acute inflammation results from infection or trauma, it is triggered along the same pathway. Adjuvants used for all current vaccines function through the activation of the TLR pathway. The most potent adjuvant, Freund's complete adjuvant is a water-in-oil emulsion containing mycobacterial cell wall components that activate TLR-1MTLR-2 and TLR-4. The simplest adjuvant, alum (aluminium hydroxide) includes molecules involved in antigen presentation in monocytes, MHC class II, CD40, CD54, CD58, CD83 and CD86; drives monocyte differentiation toward a dendritic cell like morphology;

and induces secretions of IL-4, a cytokine with potent antibody production enhancing properties.

ALVEOLAR MACROPHAGES

Alveolar Macrophages (AM) are bone marrow-derived cells that can be differentiated from blood monocytes after they have emigrated into the tissues. Alveolar macrophages are located at the air-tissue interface in the lung, and are the first cells, which interact with inhaled organisms and antigens. These cells inhabit the various compartments of the lung, differentiating into mature macrophages, surrounding themselves in phagolysosomes once they engulf ingested material into the alveoli. Alveolar macrophages produce lysozyme and defensins, which have bactericidal properties that are capable of destroying gram-positive and gram-negative bacteria and fungi. Reactive oxygen intermediates (superoxide anion, hydrogen peroxide, hydroxyl radicals) or reactive nitrogen intermediates [nitric oxide (NO), nitrites or nitrates] are also involved in destroying microorganisms and tumor cells.

Macrophages also produce macrophage metalloelastases, collagenase, metalloproteases (MMP1, MMP9) fibroblast growth factors, such as transforming growth factor (TGF) or platelet-derived growth factor that help in lung repair and remodeling. Intercellular adhesion molecule-1 ICAM-1, CD54) and vascular cell adhesion molecule (VCAM-1, CD106) are adhesion molecules of the immunoglobulin super-family. Adhesion to the vascular endothelium mediated through ICAM-1/VCAM-1-integrin interactions is a key step in the emigration of white blood cells to the sites of inflammation. It has also been shown that they play an important role in the adherence of effector cells, such as AM to the respiratory epithelium. All these inflammatory mediators together play a crucial role in the orchestration of an inflammatory response, particularly in neutrophil recruitment. Recent studies suggest that cytokines and chemokines originate from AM, and from other cells such as epithelial cells.[48]

The ability of macrophages to interact with microbes is mediated by the surface receptors capable of binding specific ligands, including toxins, polysaccharides, lipopolysaccharides, complement proteins and immunoglobulins. Pulmonary macrophages release the cytokines TNF-α and interleukin-1β (IL-1β), as well as the chemokines, Monocyte Chemoattractant Protein-1 (MCP-1), macrophage inflammatory protein -1β (MIP-1β), and growth factors.[49] Inflammatory cytokines will favor the activation of the neighboring cells and attract several inflammatory elements from the blood. Stimulation of macrophages or mast cells through their Toll-like receptors leads to the synthesis and the secretion of proinflammatory cytokines and lipid mediators, thereby initiating the inflammatory response that recruits both soluble immune components and immune cells from the blood. TLR stimulation of dendritic cells induces the initiation of an adaptive immune response.

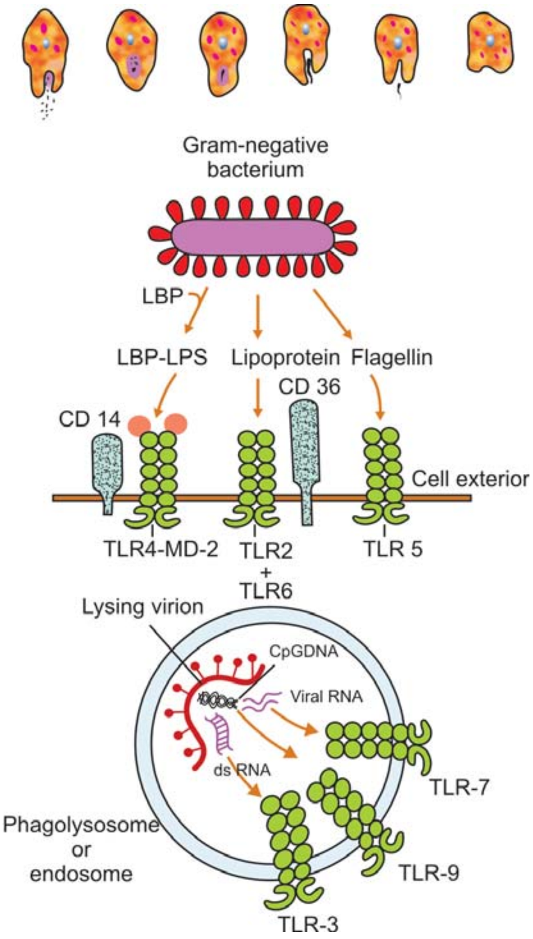

Fig. 12.9: Toll like receptors in phagocytosis

TLR's are involved in the uptake of pathogens such as bacteria or viruses by alveolar and airway macrophages (Fig. 12.9). TLRs also play a vital role in the maturation of Dendritic Cells (DCs) and hence play a key role in the adaptive protection of the lung against bacteria and viruses. TLR2 plays an important role in mediating inflammatory responses to gram-positive microorganisms and mycobacterial products such as peptidoglycan, lipoteichoic acid, lipoproteins and lipoarabinomannan.

Interstitial macrophages are located within the interstitial tissue surrounding the bronchioles and vessels. The ability of the interstitial macrophages to ingest materials appears variable and the phagocytic activity of interstitial macrophages is reduced compared to that of alveolar macrophages. Interstitial macrophages express the higher levels of major histocompatibility complex class II and CD54 and exhibit increased antigen presenting activity compared to both alveolar macrophages and blood monocytes.

Adaptive Immunity

Following inhalation, the lung is continuously bombarded with inhaled antigens, pathogenic and nonpathogenic particulate matter that have the potential to activate the adaptive immune system. Similar to the development of oral tolerance against commonly encountered antigens and microorganisms in the gut, the lung has developed a mechanism to functionally discriminate between material that can be disposed off through the innate immune system and that necessitates the activation of the adaptive immune system. A state of tolerance to commonly inhaled antigens is induced in the normal lung in which T-cell responses are actively suppressed both at the levels of the T cell itself and by the down regulation of antigen presenting functions of pulmonary DCs by resident alveolar macrophages. After the initiation of an inflammatory event or after disruption of the barrier function of the airway or alveolar epithelium, T-cell-mediated responses are rapidly activated to protect the lung. Alveolar macrophages suppress T-cell activation in the normal lung and this fine control against commonly encountered nonpathogenic organisms can be down-regulated during lung infections. The mechanisms underlying the induction of macrophage immunosuppressive activity depends on (1) NO, (2) Prostaglandin E2 (PGE2), and (3) immunosuppressive cytokines, especially TGF-β and IL-10. However, the relative contribution of each of these molecules is not completely clear.

Th1 or Th2 RESPONSES (Type1 Type2 Response)

The helper T-cells produce enormous amount of two types of cytokines: Th1 and Th2 (Fig. 12.10). Th1 and Th2 responses are polarized responses by the body's T-helper cells when faced by pathogens. T-lymphocytes recognize foreign antigens and produce cytokines that are responsible for the biological effects on the immune system. The Th1 cytokines produced by the helper T-cells produce a proinflammatory response. The Th2 cytokines produce an anti-inflammatory response, but promote allergic responses. The original observation that mouse CD4+ T-cell clones could be divided into two different sets based on their pattern of cytokine expression has

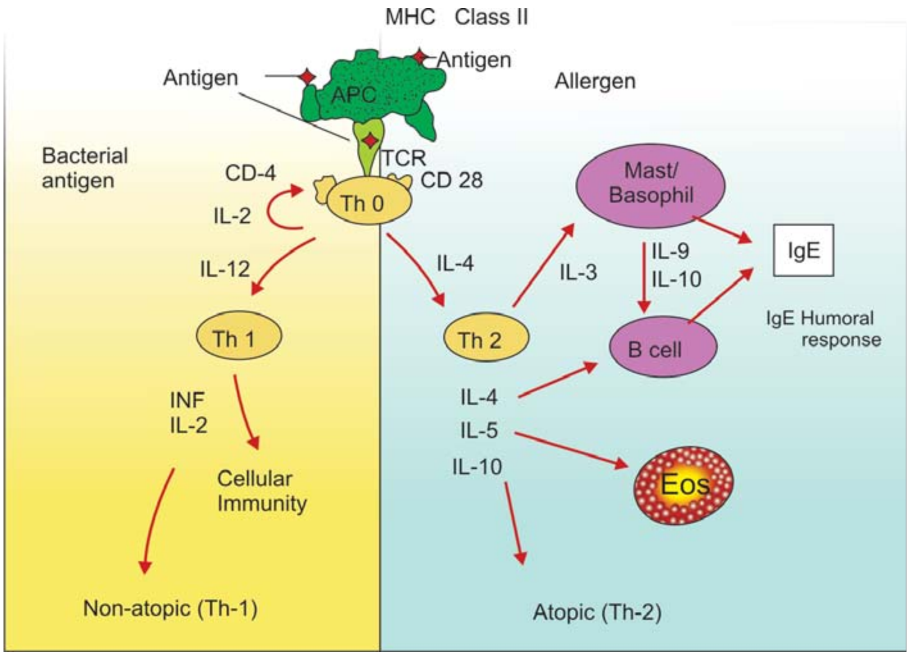

Fig. 12.10: Production of cytokines by T cells

become the paradigm for heterogeneity within the T-cell response *in vitro* and *in vivo*.[50] Th1 and Th2 cells are thought to be derived from a nonpolarized, naive Th0 precursor that produced a wide range of cytokines, that can differentiate after activation in the presence of IL-12 and IL-18 (from DCs) into Th1 cells that secrete IL-2, IFN-g and Lymphotoxin (LT) or in the presence of IL-4 (from B cells or lymphoid DCs) into Th2 cells that secrete IL-4, IL-5 and IL-10. This initial polarization of the response towards Th1 or Th2 is then self-perpetuating as Th1 cytokines enhance further Th1 responses and down regulate Th2 cytokines, and vice versa.

The Th1-type cytokines produce inflammation to kill intracellular organisms (viruses and certain bacteria such as *Listeria* and *Mycobacterium tuberculosis)*. These cytokines also perpetuate any form of autoimmune response, and can cause cell-mediated allergies. The Th2 cytokines counteract the effects of the Th1 cytokines – they have an anti-inflammatory action, but they also help to kill extracellular pathogens (which live outside the body's cells and are exposed to antibodies in blood and other body fluids). The Th2 cytokines induce a pronounced allergic response (e.g.) IgE-mediated allergies or asthma (Fig. 12.10).[51]

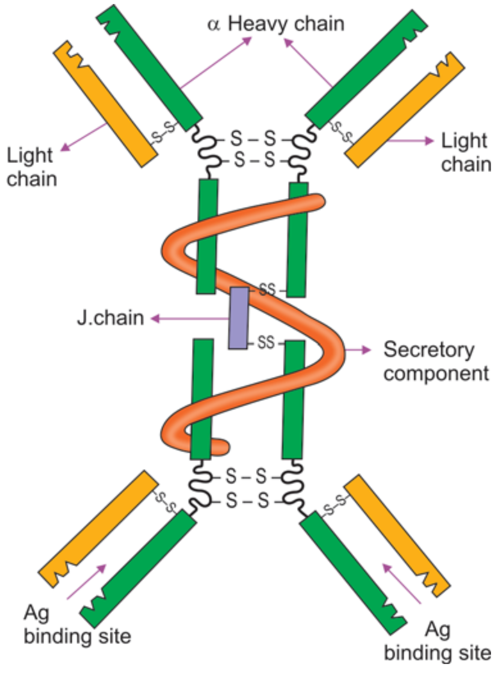

Fig. 12.11: Structure of immunoglobulin (IgA) with secretory component

Role of Immunoglobulins

The respiratory tract immunoglobulins are produced by passive diffusion from the vascular compartment across the lung tissue, and locally in the respiratory tract by the B cells within lung tissue. The bronchial mucosa is the most active site for production. The immunoglobulin reaches the airways lumina either by passive diffusion or by active transport through epithelial cells.

Experiments in animal models indicate that exposure to low doses of antigens usually does not evoke a primary antibody response. The low doses of antigens are cleared by the nonspecific defense mechanisms such as by mucociliary blanket and nonspecific phagocytosis. The dose of antigen required to elicit an antibody response has to be large to overcome the nonspecific defense mechanisms and induce pulmonary inflammation leading to the translocation of the antigen from the lung to the draining LALN.[52] Dendritic cells play an important role in antigen uptake, transport and presentation to the LALN. The nonspecific pulmonary inflammation allows for the recruitment of Antibody Forming Cells (AFC's), which are generated in the LALN and are released into efferent lymphatics and blood and subsequently reside in the lung parenchyma. It has been demonstrated in a dog model that B cells recruited to and/or produced in the lung interstitium are able to produce antibody for years after local immunization and challenge because of production of immune memory cells only in the immunized lung lobe.

i. *IgA:* Local production and active secretion of total IgA into human respiratory tract can be assessed by Bronchoalveolar Lavage (BAL) specimen analysis. The IgA producing plasma cells are found in large numbers in glands and lamina propria of the major bronchi, small bronchi, bronchioles and alveolar septa. Majority of the BAL IgA is polymeric sIgA. Subclass of IgA, IgA2 constitutes 10% to 20% of total IgA in blood and about 30% of total IgA in BAL. Free Secretory Component (SC) (Fig. 12.11) can also be recovered, however, the recovery of SC is markedly reduced in smokers. IgA deficiency, defined as IgA level less than 5 mg/dl, is a relatively common disorder (prevalence estimated as 1/300 to 1/2,000). It may be associated with IgG subclass deficiency, the infections commonly noted include recurrent pneumonia, bronchiectasis, COPD and chronic bronchitis. IgE-mediated allergy is strongly associated with IgA deficiency and allergic asthma frequently occurs in these patients.
ii. *IgG:* Respiratory tract IgG is mostly serum derived. All IgG subclasses have been identified in human

BAL. Increased levels of IgG1 (in both serum and lavage) and of IgG3 has been documented in smokers. IgG subclass deficiency is associated with a variety of infections, the clinical manifestation depends on the subclass or subclasses involved. For example, deficiency of IgG1 is associated with a lifelong increased susceptibility to pyogenic infection and progressive deteriorating lung disease. IgG1 deficiency is most often linked with IgG2 and IgG3 deficiency. IgG2 deficiency results in decreased antibody production to polysaccharide antigen. Such patients frequently have infections with capsulated microorganisms, develop sinusitis, otitis media, and pneumonias leading to chronic lung disease or recurrent meningitis. IgG2 subclass deficiency is associated with IgA deficiency. IgG3 subclass deficiency also results in recurrent respiratory tract infections and chronic lung disease.

It is difficult to demonstrate IgG4 subclass deficiency, since 30% of the general population may have undetectable levels using standard methods. Use of extremely sensitive techniques, that can detect IgG4 levels as low as 0.005 mg/dl, have shown that patients develop recurrent lung infections and/or bronchiectasis. Some individuals with IgG subclass deficiency may be completely normal and healthy in whom a complete evaluation of the patient's ability to make antibody to tetanus toxoid and pneumococcal vaccine must be undertaken.[53]

iii. *IgE:* IgE appears to be locally produced in the respiratory tract. IgE bound to histamine-containing cells can also be identified in the human lung by BAL. Elevated BAL Ig levels have been noted in hypersensitivity pneumonitis, idiopathic pulmonary fibrosis, sarcoidosis and Acquired Immunodeficiency Syndrome (AIDS). However, it is unclear whether increased IgE levels are of pathogenic importance or simply a marker of some other underlying disease process.

iv. *Humoral B cell deficiency:* Sinopulmonary infections (such as otitis media, sinusitis bronchitis and pneumonia and bacteremia resulting in sepsis or meningitis) can occur in individuals with humoral (B-cell) deficiency. Encapsulated organisms, such as *S. pneumoniae*, *H influenzae* and *Neisseria meningitides* or gram-negative organisms are usually the etiologic agents. Recurrent infection leads to chronic diseases such as bronchiectasis and/or respiratory dysfunction. There may be a complete failure of B-cell development as characterized by Bruton's agammaglobulinemia to selective IgG subclass deficiency. A number of molecular defects with B-cell deficiency have been described. Usually B-cell deficiencies are found in children and recently there are reports in older individuals with primary immunodeficiency diseases.

Common variable immune deficiency presents as a hypogammaglobulinemia, decreased antigen-specific antibody function and increased recurrent infections.[54]

IMPACT OF BACTERIA AND VIRUSES ON LUNG IMMUNOLOGY

In healthy individuals, the lower airways are sterile and contain very few goblet cells. In patients with mucus hypersecretory diseases, the lower airways are often infected with bacteria or viruses and contain many goblet cells. The importance of bacteria and viruses in the pathogenesis of asthma, chronic bronchitis, cystic fibrosis, and in exacerbations of these diseases has become clear.[55] An important mechanism appears to involve the recruitment of neutrophil chemokines produced by epithelial cells infected with bacteria and viruses. Infection with rhinovirus (RV), the most common respiratory virus, associated with asthma exacerbations induces mucus hypersecretion in airway epithelial cells.[56] RV infection was associated with IL-8 levels and with increased neutrophils in lavage fluid. Virus replication also induces IL8 synthesis by airway epithelial cells.[57,58]

In COPD and cystic fibrosis patients, gram-negative bacteria, such as *P. aeruginosa* and *Chlamydia pneumonia* colonize the lower airways and cause acute exacerbations of disease. These exacerbations are associated with excessive mucus formation. The elevated sputum levels of IL-8 neutrophils, neutrophil elastase and DNA, suggest the role of bacteria in neutrophil recruitment and destruction in the airway lumen.[59] *P. aeruginosa* and *C. pneumoniae* induce IL-8 production by airway epithelial cells. In addition to its role in neutrophil recruitment, IL-8 inhibits neutrophil apoptosis, (self-death) resulting in increased neutrophils within the airways. Infection of mucus plugs in the lower airways where cough is ineffective, further leads to neutrophil-dependent mucin production.[60,61] *P. aeruginosa* deposited on mucus surfaces penetrate into hypoxic zones within mucus plugs, where they evade phagocytosis, multiply and secrete substances that promote neutrophil recruitment. The mucus plugs promote neutrophil necrosis via the entrapment of neutrophils in a microenvironment characterized by large numbers of bacteria, extracellular acidosis and very low oxygen tension causing the release of neutrophil products, such as reactive oxygen species that can induce further mucin production.

Double stranded RNA, a product of single stranded RNA virus replication has been shown to induce mucin in airway epithelial cells.[62] This occurs more frequently in chronic bronchitis and also in cystic fibrosis, in which hydration of submucosal gland mucins can result in the retrograde movement of mucus. Retrograde aspiration of bacteria and mucus into the peripheral airways may lead to bacterial infection, goblet cell formation, goblet cell degranulation and mucus plugging in the periphery.

HLA AND MYCOBACTERIAL DISEASES

There is a possible genetic predisposition to particular bacterial/mycobacterial diseases. Early studies on HLA variation established its relevance in susceptibility to TB and leprosy, especially in Asian population.[63] Children who are homozygous for mutations in the IFN-α receptor gene have been found to be susceptible to weakly pathogenic mycobacteria, including the Calmette-Guérin bacillus vaccine, and have a poor prognosis. The role of genetic factors in various lung defenses is a subject of further investigations.

Antibacterial Drugs

Nusrat Shafiq, Samir Malhotra

INTRODUCTION

Antibacterials are commonly, many times inappropriately, used for upper and lower respiratory tract infections. Therapeutic concentrations in respiratory secretions, in excess of the Minimum Inhibitory Concentration (MIC) for that pathogen are necessary for the successful treatment of pulmonary infections. Concept of blood-lung barrier on the lines of blood-brain barrier has been also proposed. Ability of drugs to penetrate respiratory secretions depends on factors such as molecular size of the antibacterial, lipid solubility and degree of ionization. In order to achieve higher local concentrations, especially those of polymyxins and aminoglycosides, some investigators in the past have administered them through the endotracheal route. However, the use of antibiotic aerosols continues to remain controversial.

Pharmacokinetic properties of the antibiotics, their ability to reach the site of infection, their half-lives (how many times per day) and presence of comorbid conditions (impaired renal or hepatic functions) may also determine the choice of drugs. For instance, the doses of drugs eliminated by kidneys (aminoglycosides, vancomycin, others) or metabolized by liver (chloramphenicol) must be adjusted in the presence of impaired renal or hepatic function, respectively.

Moreover, side effect profiles and drug interactions would need further consideration. Some side effects like gastrointestinal (nausea, vomiting, diarrhea) and drug rash can occur with the majority of the antibiotics. Hypersensitivity reactions can occur with most antimicrobials especially, but not exclusively, with parenteral use. Bone marrow suppression has also been reported with most of the antimicrobials. However, some may be typical for a class, e.g. nephrotoxicity for aminoglycosides, and QT prolongation for quinolones like moxifloxacin and sparfloxacin.

Cost factors are important especially in countries with sparse cover of health insurance. Most of the novel antimicrobials must be used sparingly, not only due to cost factors, but also to save the drugs from misuse and development of resistance.

The following chapter focuses on the pharmacological aspects of antibacterials used for the empiric management of respiratory tract infections.

BETA-LACTAMS

Beta-lactam group includes penicillins, cephalosporins, carbapenems and monobactams. The name of this group of agents derives from basic structure of thiazolidine ring connected to a beta-lactam ring to which a side chain is attached. They inhibit the synthesis of peptidoglycan, an important component of cell walls of the bacteria. Specifically, the final step of transpeptidation is inhibited by penicillins. Additionally, penicillins and cephalosporins bind to Penicillin-Binding Proteins (PBPs) bringing about lytic, as well as nonlytic killing. Alteration in PBPs and production of beta-lactamases are the important mechanisms of resistance, which is not inherently present in some bacteria. At least four types of betalactamases are known. Class A -beta-lactamases, also called extended spectrum beta-lactamases, inhibit penicillins, cephalosporins and carbapenems. Class B beta-lactamases destroy all beta-lactams except aztreonam. Class C beta-lactamases are against cephalosporins while Class D beta-lactamases degrade cloxacillin.

1. Penicillins

Penicillin G (benzylpenicillin) is the only naturally obtained penicillin used clinically; several semisynthetic penicillins with desired properties are derived from modification of 6-aminopenicillanic acid. Various classes of penicillin are:

a. Highly active against sensitive strains of gram-positive cocci, but ineffective against *Staphylococcus aureus*, which produces penicillinase: Penicillin G, Benzathine penicillin, Procaine penicillin, Penicillin V.

b. Penicillinase-resistant penicillins, effective against *S. aureus* and *Staphylococcus epidermidis* that are methicillin susceptible: Methicillin, Nafcillin, Oxacillin, Cloxacillin, Dicloxacillin, Flucloxacillin.

c. Penicillins effective against gram-negative organisms, such as *Haemophilus influenzae, Escherichia coli* and *P. mirabilis:* Ampicillin, Amoxicillin, Bacampicillin, Metampicillin, Pivampicillin.

   The last three are prodrugs and are hydrolyzed to ampicillin *in vivo.*

   Penicillins with activity against *Pseudomonas*, *Enterobacteriaceae* and *Proteus* species (carboxypenicillins): Carbenicillin, Ticarcillin. These penicillins are inferior to ampicillin against gram-positive cocci.

d. Penicillins with activity against *Pseudomonas*, *Klebsiella* (ureidopenicillins): Mezlocillin, Azlocillin.

e. Penicillins with activity against *Pseudomonas*, *Klebsiella* and gram-positive cocci: Piperacillin.

Individual Penicillins

i. *Penicillin G (Crystalline penicillin, benzylpenicillin):* Susceptible organisms include *Corynebacterium diphtheriae*, *Peptostreptococcus spp.*, non-beta-lactamase-producing staphylococci and streptococci, including *Streptococcus agalactiae* (group B), *Streptococcus pneumoniae* (pneumococci), *Streptococcus pyogenes* (group A), and some viridans streptococci; of these Group A Streptococci are an occasional cause of pneumonia in previously healthy adults. These organisms are responsible for 20% to 40% cases of exudative pharyngitis in children. Group B streptococci are the most common cause of pneumonia in neonates. Enterococci are relatively insensitive to penicillins. *Pasteurella multocida*, *Streptobacillus moniliformis* and *Spirillum minus* (or *minor*) are also susceptible to penicillins. *Actinomyces* show good susceptibility to penicillins. Most strains of *S. aureus* are resistant to penicillin. *Bacillus anthracis* and *C. diphtheriae* are other susceptible pathogens, which may cause respiratory tract infections. Resistance to staphylococcus, *S. pneumoniae*, pneumococci and *H. influenzae* are common.

Pharmacokinetics: Given intramuscularly, peak plasma concentration is reached in 15–20 minutes. It is widely distributed in the body and excreted mainly through renal tubular secretion. Renal tubular secretion may be inhibited by adding probenecid. Doses of 600 mg of benzylpenicillin sodium or potassium are considered equivalent to 1 MU. Dose reduction (25–50%) may be required if creatinine clearance decreases.

Indications and dosage: Str. pneumoniae has usually been considered to be sensitive to penicillins, but there is increasing prevalence of resistance although there are marked geographical differences. A survey conducted across 25 countries from 1999 to 2000 reported prevalence of resistance from 7.8% to 71.5%.[1] However, penicillin G remains agent of choice for serious infections like bacteremia, empyema, severe pneumonia, pericarditis, endocarditis, meningitis, and others caused by sensitive strains of the gram-positive species mentioned above. It may also be considered for sensitive strains of pneumococci.

The Drug-Resistant Streptococcus pneumoniae Therapeutic Working Group (DRSP) argued that penicillin susceptibility categories should be shifted upward for pneumococcal pneumonia so that the susceptible category includes all isolates with MIC of no greater than 1 μg ml^{-1}, the intermediate category includes isolates with MIC of 2 μg ml^{-1} and the resistant category includes isolates with MIC of no less than 4 μg ml^{-1}. The group suggested the aforementioned classification in order to parallel penicillin resistance categories with clinical outcomes.[2] The dose of 20–24 MU of penicillin G should be administered daily by constant intravenous infusion (IV) or 1–2 million units intramuscularly (IM) every 2 hours. Therapy should be continued for three to five days after the patient becomes afebrile. Each million units contains approximately 6.8 mg (0.3 mEq) of sodium and 65.6 mg (1.68 mEq) of potassium.

In splenectomised patients with compromised immunity status, phenoxymethylpenicillin

(penicillin V) may be offered for lifelong prophylaxis against pneumococcal and *H. influenzae* infections. Penicillin G is the drug of choice for actinomycosis, 12–20 MU of penicillin G are given IV. Combination with aminoglycosides is synergistic and is usually employed for enterococcal infections. However, with bacteriostatic drugs like chloramphenicol and tetracyclines, antagonism may be seen.

ii. *Methicillin:* The antimicrobial spectrum is largely similar to benzylpenicillin. It is active against both penicillinase-producing and nonpenicillinase-producing staphylococci. This may be due to the fact that resistance to methicillin is due to alteration in penicillin-binding protein and not due to penicillinase production. Methicillin is also effective against *S. pyogenes* (group A beta-hemolytic streptococci), *Str. pneumoniae*, and some viridans streptococci. Its activity against penicillin-sensitive staphylococci and streptococci is less than that of benzylpenicillin.

It is inactivated by gastric acid and should be administered parenterally. Distribution is wide and nearly 80% of the drug is excreted unchanged in the urine. Since the drug is inactivated by gastric acid, it must be given by injection. Peak plasma concentrations are attained within 0.5 to 1 hour of an intramuscular injection. The half-life of methicillin in patients with normal creatinine clearance is 0.5 to 1 hour, but may increase to 3 to 6 hours in renal impairment. The majority is rapidly excreted by tubular secretion and glomerular filtration; up to 80% of an injected dose has been detected unchanged in the urine. Plasma concentrations are enhanced by probenecid.

It is not commonly used in clinical practice, but may be used to treat infections caused by susceptible gram-positive bacteria. The usual adult dose is 250 mg four times daily intramuscularly or 0.25 to 1 g four times daily by slow intravenous injection (over three to four minutes). The dose may be doubled in severe infections. Interstitial nephritis is an important adverse effect.

iii. *Oxacillin:* It is an orally active oxazolyl penicillin. Though it is active against sensitive strains of penicillinase producing staphylococci, it is not considered for the treatment of serious infections caused by penicillinase-producing staphylococci.

It is incompletely absorbed from the Gastrointestinal Tract (GIT) and the absorption is affected by the presence of food which is why a gap of one to two hours between food and drug intake is recommended. Peak plasma concentration is achieved in one hour after oral administration. Oxacillin is excreted both in the urine and bile.

Its indications are similar to flucloxacillin. It is administered orally in a dose of 1 g twice a day. Hepatitis may occasionally occur.

iv. *Flucloxacillin:* Penicillinase and non-penicillinase producing staphylococci and Strep pneumoniae are susceptible to flucloxacillin though the activity of benzylpenicillin is more against these organisms as compared to flucloxacillin. In some centers it continues to remain a good choice for the empirical treatment of staphylococcal infections in intensive care units.[3]

Absorption through gastrointestinal tract is good and peak plasma concentration is achieved in one hour. It may also be given by intramuscular injection. The oral and parenteral dose is 250 mg four times daily. Unchanged drug and the metabolite is excreted in the urine and bile. A spacing of 30 minutes from meals is recommended.

Susceptible gram-positive infections, including the recently important infection due to Panton-Valentine Leukocidin (PVL-) producing *S. aureus,* which is emerging as a serious problem worldwide. There has been an increase in the incidence of necrotizing lung infections in otherwise healthy young people with a very high mortality associated with these strains. Flucloxacillin (4 g tid) and rifampicin may be given empirically.[4] The usual dose is 250 mg four times daily orally or intramuscularly. Its IV dose is 0.25 to 1 g four times daily by slow injection over 3 to 4 minutes or by IV infusion. The dose may be doubled in severe infections.

Hepatitis and cholestatic jaundice may occur occasionally. The side effect may be delayed for more than two months after stopping the drug. Flucloxacillin is a pregnane X receptor (PXR) agonist at pharmacologically relevant concentrations, and a functionally significant upstream PXR polymorphism is a risk factor for flucloxacillin-induced liver injury.[5] It should be used with caution in patients with hepatic dysfunction.

v. *Cloxacillin:* Its spectrum and other features are similar to those of flucloxacillin. It is incompletely absorbed from the gastrointestinal tract. Peak plasma concentration after oral administration is achieved in one to two hours. Food affects its absorption and an interval of half an hour is required between the administration of the drug and food intake. Indications and dosage are similar to flucloxacillin. It is administered in a dose of 250–500 mg six hourly.

vi. *Dicloxacillin:* Absorption from the gastrointestinal tract is better than that of cloxacillin. Rest of the profile is similar to cloxacillin.

vii. *Ampicillin:* Ampicillin has a broader spectrum of activity than benzyl penicillin. In addition to gram-positive bacteria, some gram-negative bacteria such as *H. Influenzae* are susceptible to ampicillin. It is well absorbed after oral administration. Food hampers its absorption and hence it should preferably be taken 30 minutes before meals. Peak plasma concentrations are reached in one to two hours after oral administration. It undergoes enterohepatic circulation. Dose adjustment is required in renal impairment.

It is indicated for the initial treatment of acute tracheobronchitis of I, II and III Class. As a therapy for acute exacerbation of tracheobronchitis, it offers modest benefit at best.[6] Ampicillin in a dose of 1–2 g daily in 3–4 divided doses for 7–10 days orally or IV, either alone or in combination with beta-lactamase inhibitor (sulbactam) is indicated for the empirical therapy of pneumonia in adults—pneumonia with chronic bronchitis and for suspected pneumococcal pneumonia if resistance to ampicillin is not common.

Ampicillin-sulbactam is also indicated for empirical antimicrobial therapy for pneumonia in pediatric patients of less than one month of age when Group B streptococcus, *H. influenzae* and *S. aureus* are the usual pathogens. The combination is also indicated for the empirical therapy of pneumonia in pediatric patients of three months to six years of age in whom the suspected organisms include pneumococcus or *H. influenzae.* Ampicillin-resistant *H. influenzae* may be susceptible to ampicillin-sulbactam combination. Ampicillin for three months has been successfully used in patients with actinomycosis or a follow-up therapy to ceftriaxone. Benzylpenicillin, however, continues to remain the treatment of choice for this condition. Recently, aerosolized ampicillin was reported for the treatment of *S. aureus* lung infection in a 14-year-old patient of cystic fibrosis.[7]

Salient adverse effects: Urticarial and maculopapular rash are known to occur with ampicillin, the former represents hypersensitivity. Maculopapular rash may occur seven days after the drug administration. Appearance of rash is not necessarily an indication for stopping the use of penicillins. However, sensitivity testing should be undertaken before use. Patients with infectious mononucleosis, lymphatic leukemia and HIV infection are particularly susceptible to ampicillin induced rash. Caution should be exercised with the subsequent use of penicillin. Studies in adults indicate that ampicillin, in a dose-dependent manner, impairs platelet function and moderately prolongs the bleeding time (generally by 60 to 90 seconds). A similar increase in bleeding time is also noted in pediatric patients.[8] Diarrhea, hepatitis, cholestatic jaundice, erythema multiforme, Stevens-Johnson syndrome and toxic epidermolytic necrosis have all been reported with its use.

viii. *Amoxicillin:* Amoxicillin is a 4-hydroxy analog of ampicillin. The antimicrobial spectrum of amoxicillin is similar to that of ampicillin. It is not inactivated by gastric acid. Compared to ampicillin, it is absorbed more rapidly and completely. Half-life may increase to nearly 20 hours in severe renal impairment. It crosses the placenta and small amount may be secreted in breast milk. It is largely excreted by tubular secretion and glomerular filtration.

The indications for amoxicillin are similar to those of ampicillin. Addition of beta-lactamase inhibitor, clavulanic acid extends the spectrum of amoxicillin to include *H. influenzae* and *Moraxella catarrhalis*. In a recent Cochrane review done to evaluate effective antibiotics for ambulatory pediatric patients with community acquired pneumonia, amoxicillin had similar failure rates as those of co-trimoxazole.[9] The authors concluded that for severe pneumonia without hypoxia, oral amoxicillin may be an alternative to injectable penicillin in hospitalized children; however, for ambulatory treatment of such patients with oral antibiotics, more studies in community settings are required.[9] Its dose is 250–500 mg three times a day orally. An extended release preparation of amoxicillin is available in some countries. It is generally used for pharyngitis due to *S. pyogenes* and it is given as a single daily dose for 10 days.

The incidence of diarrhea is less than that of ampicillin. Hepatitis and cholestatic jaundice have been reported with the use of amoxicillin. These have largely been seen when it is used in combination with clavulanic acid.

ix. *Carbenicillin:* The antimicrobial spectrum is similar to that of benzylpenicillin and is penicillinase susceptible. However, it is not effective against most strains of *S. aureus* , *Enterococcus* and *Klebsiella*. In addition, it is also effective against *P. aeruginosa*. It has largely been superseded by piperacillin and ticarcillin for most of its indications.

It is not absorbed through gastrointestinal tract and needs to be given either intramuscularly or intravenously. However, carbenicillin indanyl is a prodrug, designed for oral administration. The carbenicillin, which is released from this prodrug does not achieve sufficient concentrations in the blood and is used only for the treatment of urinary tract infections. The half-life of carbenicillin is increased in renal impairment.

Indications and dosage are similar as for ticarcillin. Dose-dependent coagulation defect may occur. Congestive heart failure may result due to the sodium ions present in carbenicillin sodium. Carbenicillin sodium contains about 5 mEq Na^+ per gram of drug, and this will result in the administration of more than 100 mEq Na^+ when patients are treated for *P. aeruginosa* infections. Carbenicillin constitutes large amount of nonreabsorbable anion and may cause hypokalemia.

x. *Ticarcillin:* It is two to four times more active against *P. aeruginosa* than carbenicillin. It is given by intravenous route. The drug is eliminated renally and caution should be exercised in patients with reduced creatinine clearance. The maintenance dose needs to be modified from 2 g every 12 hours to 2 g every 24 hours for creatinine clearance of 10 ml min to 30 ml/min respectively. Half-life of the drug may be shortened in patients with cystic fibrosis.

   When given with clavulanic acid, the activity of ticarcillin is extended to beta-lactamase producing organisms such as staphylococci, enterococci and *H. influenzae*. It needs to be noted that addition of clavulanic acid does not increase its activity against *P. aeruginosa*. Ticarcillin-clavulanate is considered for the empirical antimicrobial therapy for pneumonia in adults with a history of alcoholism. The suspected organisms in these cases are Pneumococcus, *Klebsiella pneumoniae*, *S. aureus*, *H. influenzae* and possibly mouth anaerobes. More than 70% of pseudomonas isolates obtained from patients of cystic fibrosis may be susceptible to ticarcillin.[10] It is given by injection as the sodium salt in the doses of 200 to 300 mg/kg daily by intravenous infusion in four or six divided doses. The adverse effects of cholestatic jaundice and hepatitis seen with ticarcillin/clavulanic acid are mainly due to the clavulanic acid component. The defects of platelet aggregation are known to occur.

xi. *Piperacillin:* Its spectrum includes most strains of *P. aeruginosa,* Enterobacteriaceae (non-beta-lactamase producing), many *Bacteroides spp.,* and *Enterococcus faecalis*. In combination with a beta-lactamase inhibitor (*piperacillin-tazobactam),* it has the broadest antibacterial spectrum out of all penicillins. Peak plasma concentrations are achieved in half to one hour. High biliary concentrations are also achieved. Recently, it has been suggested that the plasma concentrations of piperacillin should be monitored to achieve better outcomes.[11] The combination with tazobactam is indicated for the empiric therapy of pneumonia in adults who have a history of alcoholism and those with nosocomial pneumonia. It is also indicated in patients with community-acquired pneumonia in whom pseudomonas infection is suspected. In life-threatening infections, particularly those caused by *Pseudomonas* or *Klebsiella spp*., it should be given in a dose of not less than 16 g/day up to a maximum dose of 24 g/day. The combination is also indicated for use in *Acinetobacter baumannii* infection, a causative organism of ventilator associated pneumonia.

xii. *Mezlocillin and azlocillin:* These penicillins do not find recommendations in most guidelines for the treatment of respiratory tract infections. They have good activity against pseudomonas.

Adverse Effects of Penicillins

Hypersensitivity reactions are not only the most common adverse reactions (up to 10%) associated with penicillins, but can also be fatal. The manifestations include the occurrence of maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens-Johnson syndrome and anaphylaxis. There is a wide variation in their presentation; any history of hypersensitivity reaction to penicillin precludes its use in future.

All types of skin rashes are known to occur with their use. Rarely thrombocytopenic purpura and Henoch-Schonlein purpura may occur. Exfoliative dermatitis are erythema multiforme may also occur. Serum sickness characterized by fever, leukopenia, splenomegaly, arthralgia , arthritis, purpura, electrocardiographic changes may sometimes occur after one week of treatment with penicillin. Skin vasculitis, positive Coomb's reaction and reversible neutropenia may also occur. The latter is more commonly seen with the use of nafcillin. Fever, eosinophilia, reversible interstitial nephritis (mainly with methicillin) are sometimes observed.

Angioedema and anaphylaxis constitute the most serious adverse reactions associated with the use of penicillins. These can occur with any route of administration although more commonly with the parenteral routes. Anaphylactic and anaphylactoid reaction constitute medical emergency and occur with an incidence of 0.004% to 0.04%. It presents with severe bronchoconstriction, drop in blood pressure, nausea, vomiting, abdominal pain and diarrhea. Prior skin testing with a small amount of penicillin (a few units) is mandatory before the use of penicillins.

Oral penicillins are likely to cause GI adverse effects (diarrhea, nausea) in a significant proportion of patients. Pseudomembranous colitis can occur with almost all antibiotics, including penicillins (especially ampicillin and amoxicillin). Hematological adverse effects (like hemolytic anemia, neutropenia, abnormal platelet function leading to prolongation of bleeding time), convulsions, encephalopathy (intrathecal administration), and electrolyte imbalance can occur. Hepatitis and cholestatic jaundice are rare (especially with flucloxacillin, oxacillin, and amoxicillin/ticarcillin-clavulanic acid combination). Nephropathy and interstitial nephritis (mainly with methicillin) can occur.

2. Cephalosporins

The cephalosporins or cephem antibacterials are semi-synthetic antibacterials derived from cephalosporin C, a natural antibacterial produced by the mould *Cephalosporium acremonium*. The hydrolysis product of cephalosporin, 7-aminocephalosporanic acid, has been modified to give various classes of this drug. As a consequence, four generations of cephalosporins are available with differences in their antibacterial and other pharmacological properties.

a. First-Generation Cephalosporins

Included in this group are cefazolin, cephalexin, cephalothin, cephradine, and cephadroxil. They are active against gram-positive cocci like *S. aureus* (including beta-lactamase-producing strains), *S. epidermidis*, *S.pyogenes*, *S. agalactiae*, and *S. pneumoniae,* but not against enterococci, methicillin-resistant *S. aureus,* and *S. epidermidis*), anaerobes (except *Bacteroides fragilis),* and, to a lesser extent, against gram-negative microorganisms. Activity against *M. catarrhalis, E. coli, K. pneumoniae,* and *P. mirabilis* is quite good.

i. *Cefalexin:* It is well-absorbed from the GIT, absorption may be delayed by food, but extent of absorption is not affected. Most of it is excreted unchanged in urine. It is useful in respiratory tract infections and otitis media caused by susceptible organisms, especially if penicillin cannot be used. The usual dose is 1 to 4 g daily in divided doses.

ii. *Cefazolin:* Its gastrointestinal absorption is poor, thus used parenterally (IM, IV). It is excreted unchanged in the urine. It is used for respiratory tract infections and septicemia (caused by *S. pneumoniae*, *S. aureus* (including beta-lactamase producing strains), *P. mirabilis, E. coli.* It is used in doses of 0.5 to 1 g every 6 to 12 hours (up to a maximum of 12 g) by deep IM injection or by intravenous infusion.

iii. *Cefalothin:* It is used only parenterally as it is poorly absorbed from the GIT. About two thirds is excreted in the urine and the rest is metabolized by the liver.

b. Second-Generation Cephalosporins

The antimicrobial spectrum of second generation cephalosporins (cefamandole, cefoxitin, cefaclor, loracarbef, cefuroxime, cefotetan and cefprozil) extends to include enterobacter, proteus and *Klebsiella* species. *H. inluenzae* are also susceptible to this generation.

i. *Cefamandole:* It has similar or slightly less activity than cefalothin against gram-positive bacteria, but greater stability to hydrolysis by beta-lactamases produced by gram-negative bacteria. Due to its erratic absorption, it is given as an intravenous or intramuscular preparation. It is primarily excreted by the kidneys.

   It is effective against infections caused by susceptible organisms and also for surgical prophylaxis. Prophylaxis with cefamandole (3g/day) for six months, followed by amoxicillin/clavulanate for the next 12 months has shown to decrease the incidence of postoperative pneumonia following lung resection.[12]

ii. *Cefoxitin:* It demonstrates some resistance to beta-lactamases produced by some gram-negative rods. The hallmark of cefoxitin is its activity against *B. fragilis*. It is used parenterally and almost all of it is excreted unchanged by the kidneys. It does not cross the blood-brain barrier even in the presence of inflammation. Cefoxitin is an alternative for pulmonary disease with rapidly growing opportunistic mycobacteria such as *Mycobacterium abscessus*, *Mycobacterium chelonae*, *Mycobacterium fortuitum* and *Mycobacterium gordonae*. It is also a useful antimicrobial for anaerobic and mixed infections.

iii. *Cefaclor:* It has good activity against gram-negative bacteria such as *Klebsiella* and *H. influenzae*. It may be active against some beta-lactamase producing strains of *H. influenzae*. It is used in upper and lower respiratory-tract infections and otitis media in doses of 250 to 500 mg three times a day up to a maximum of 4 g/day. It is indicated for empirical therapy of pneumococcal pneumonia in children less than five years of age an alternative to amoxicillin. It is considered as an alternative drug for acute exacerbation of bronchitis in otherwise healthy individuals.

Serum sickness like illness with the repeated use of cefaclor in children has been reported. It may increase the prothrombin time when given concomitantly with warfarin.

iv. *Loracarbef:* It is actually a carbacephem, which is slightly different structurally from cephalosporin, but has antimicrobial activity similar to that of cefaclor. It is well-absorbed orally. The indications are also same as cefaclor.

v. *Cefuroxime:* The antimicrobial spectrum of cefuroxime is similar to that of cefamandole. Cefuroxime is considered for empirical therapy of pneumonia in elderly when the likely pathogens are *Pneumococcus, Klebsiella*, *H.influenzae* or *M. catarrhalis*. Cefuroxime axetil is a prodrug of cefuroxime, after absorption it is hydrolyzed in the intestinal mucosa to cefuroxime. Cefuroxime is also used parenterally.

The major indications are bronchitis, other lower respiratory-tract infections, meningitis, otitis media and sinusitis. It is also commonly used for surgical infection prophylaxis. It may also be used for the empirical antimicrobial therapy for pneumonia in children. It may rarely cause Stevens-Johnson syndrome and toxic epidermal necrolysis.

vi. *Cefprozil:* The indications for cefprozil are similar to that of cefaclor. It has a good oral bioavailability in a single daily dose. It may also be used for the treatment of pharyngitis caused by *S. pyogenes*.

vii. *Cefotetan:* It is another second-generation antibiotic, which is seldom used in respiratory tract infections. The antimicrobial spectrum is similar to that of cefoxitin. The N-methylthiotetrazole side chain has the potential to cause hypoprothrombinemia and bleeding.

c. Third-Generation Cephalosporins

These cephalosporins, also called extended spectrum cephalosporins, have good activity against many gram-positive and gram-negative bacteria. They are more resistant to hydrolysis by beta-lactamases than the second-generation cephalosporins. Some of these agents have activity against pseudomonas.

i. *Ceftriaxone:* Among gram-negative bacteria, *in vitro* activity is seen against Enterobacteriaceae and *Klebsiella* besides *H. influenzae* and *M. catarrhalis*. There is only moderate susceptibility towards *Pseudomonas*. Among gram-positive bacteria, it is active against staphylococci and streptococci except methicillin-resistant *S. aureus*. It is not absorbed orally, about two thirds is excreted by the kidneys and the rest by liver. It crosses the blood-brain barrier even in the absence of inflammation.

It is indicated for the presumptive therapy of pneumonia in elderly patients. It is also indicated in the management of pneumococcal pneumonia in immunocompetent adults for strains with reduced susceptibility to penicillins. In adult patients with community-acquired pneumonia who are admitted in the wards, ceftriaxone or cefotaxime may be combined with a macrolide (or doxycycline). Calcium salt may rarely cause biliary sludge and pseudolithiasis. Administration of calcium salts within 48 hours of ceftriaxone administration should be avoided. Isolated fatal cases have been reported in the neonates due to the deposition of calcium ceftriaxone in the lungs. Hyperbilirubinemia may occur due to the high protein binding associated with its use. Methylthiotriazine side chain may aggravate the action of anticoagulants and disulfiram-like reaction may occur when used concomitantly with alcohol.

ii. *Cefotaxime:*. It is highly resistant to most beta-lactamases, has more activity than first- or second-generation cephalosporins against gram-negative bacteria. It is active against gram-negative bacteria like Enterobacteriaceae, *Proteus*, *Providencia*, *Salmonella*, *Serratia*, *Shigella*, *H. influenzae*, *M. catarrhalis,* and *Neisseria meningitidis*. It is also active against gram-positive bacteria, including *Staphylococcus aureus (except* methicillin-resistant), *S. epidermidis, Streptococcus agalactiae, S pneumoniae, S. pyogenes, and* anaerobic bacteria (like some strains of *B. fragilis and Clostridium difficile*).

It is not orally absorbed. The main route of elimination is renal although there is some hepatic metabolism as well that leads to the formation of active metabolite desacetylcefotaxime.

It is commonly used in intensive-care settings to treat serious infections like brain abscess, endocarditis, sepsis, meningitis, peritonitis, pneumonia and typhoid. It is also used for surgical prophylaxis. Cefotaxime/sulbactam combination may be as effective as amoxicillin-clavulanic acid in children with lower respiratory tract infections.

iii. *Ceftazidime:* Its spectrum is similar to that of cefotaxime, but the activity against *Pseudomonas* is greater. It is given parenterally, the predominant route of elimination is renal.

iv. *Ceftizoxime:* It is similar to cefotaxime, administered either by intramuscular or slow intravenous injection. It is mainly eliminated by the kidneys.

v. *Cefixime:* It is active against Enterobacteriaceae, *H. influenzae*, *M. catarrhalis* and streptococci. It is slowly and partially absorbed from the gastrointestinal tract and eliminated by the kidneys and liver. It is used for the treatment of otitis media, pharyngitis, and lower respiratory tract infections caused by susceptible organisms.

vi. *Others:* Cefpodoxime, Cefditoren and Cefdinir have spectrum similar to that of cefixime, but more active against *Staphylococcus aureus*.

d. Fourth-Generation Cephalosporins

The fourth-generation cephalosporins have an extended antibacterial spectrum. This group of cephalosporins is largely resistant to beta-lactamases. They are active against many enterobacteriacae, which are resistant to type-1 beta-lactamases. These may, however, be hydrolyzed by extended spectrum beta-lactamases. The activity against *H. influenzae* is comparable to that of cefotaxime. These agents are also active against streptococci, including penicillin-resistant streptococci and methicillin-sensitive *S. aureus*. In combination with aminoglycosides, they are indicated for the empiric therapy of nosocomial pneumonia with suspected gram-negative bacilli (*K. pneumonia*, enterobacter, *P. aeruginosa*).

i. *Cefepime:* It is used in respiratory tract and other serious infections, including in patients with febrile neutropenia caused by susceptible. It has also been used successfully in the treatment of ventilator associated pneumonia.[13] Cases of neurotoxicity manifesting as nonepileptic convulsion have been reported.[14]

ii. *Cefpirome:* Used in serious infections like pneumonia and sepsis, especially in immunocompromised patients, it is given in the doses of 1 to 2 g twice a day by IV infusion.

The adverse effects of cephalosporins are similar to those of penicillins. The gastrointestinal (diarrhea, nausea), dermatologic (rash), rash, and electrolyte disturbances (most of them are administered as sodium salts) are seen in ≥1% of patients. Less common are headache, dizziness, antibiotic associated diarrhea, superinfection and fever. Hypersensitivity reactions as seen with penicillins can occur with cephalosporins, but less commonly compared to penicillins. Cross-reactivity with penicillins is seen in about 10% of patients.[15]

3. Carbapenems

Drugs such as imipenem, meropenem, doripenem and ertapenem of this group structurally resemble penicillins and have similar mechanism of action. Carbapenems are particularly useful for the initial empirical therapy for hospitalized patients with suspected bacterial community-acquired pneumonia, patients with pneumonia in medical wards with or without previous recent history of antibiotic therapy and for patients with pneumonia in intensive care unit with suspected pseudomonas infection. For the latter, ciprofloxacin is usually combined with carbapenems. Further, meropenem may be superior to ceftazidime/aminoglycoside for the empirical treatment of ventilator-associated pneumonia.[16]

i. *Imipenem:* It is a broad spectrum antimicrobial with activity against gram-positive, gram-negative (including the beta-lactamase producing), many aerobic and anaerobic bacteria. The sensitive gram-positive organisms include most streptococci, staphylococci (penicillinase and non-penicillinase producing), *E. faecalis*, *Nocardia*, *Rhodococcus*, and *Listeria.* It is not universally active against methicillin-resistant *Staphylococcus aureus.* The gram-negative bacteria susceptible to imipenem include Enterobacteriaceae, including the *Citrobacter, Enterobacter*, *E. coli, Klebsiella, Proteus, Providencia, Salmonella, Serratia, Shigella* and *Yersinia*. It is also active against *P. aeruginosa, Acinetobacter*, *Campylobacter jejuni*, *Haemophilus influenzae* and *Neisseria.* It is also active against anaerobes like *Bacteroides* and *Clostridium difficile.* Although it is stable to most beta-lactamases, it is hydrolyzed by metallo-beta-lactamases, which could be an important cause of resistance to carbapenem treatment in ventilator-associated pneumonia.[17] *Acinetobacter baumannii* is also increasingly showing resistance to carbapenems.[18] Carbapenem-resistant *A. baumannii* (CRAB) is often associated with ventilator-associated pneumonia. Cilastatin, commonly coadministered with imipenem (see below), does not have any antimicrobial action.

Imipenem not absorbed from the GIT, needs to be administered parenterally. It is partly metabolized to toxic metabolites in the kidneys by tubular brush border enzyme (dehydropeptidase-I) and it is given along with cilastatin (inhibitor of dehydropeptidase) to increase imipenem concentrations in urine (but not serum). It is eliminated by the kidneys with a half-life of one hour.

The major indications are for infections in febrile neutropenia and other immunocompromised states, for hospital-acquired pneumonia, and sepsis. In anthrax, it is combined with other agents. Combination with cilastatin reduces the nephrotoxicity of imipenem. Seizures may be precipitated with its use in up to 1.5% of patients, especially in those with compromised renal function and prior CNS disease. Mental disturbances and confusion may also occur. It can cause reddish discoloration of urine, which may be alarming, but not dangerous.

ii. *Meropenem:* The antimicrobial spectrum of meropenem is similar to that of imipenem, but it may have activity against some imipenem-resistant *P. aeruginosa*, may be more active than imipenem against Enterobacteriaceae and less active against gram-positive organisms. Meropenem may be particularly useful in aspiration pneumonia.[19] It is similar to imipenem in most aspects, but not metabolized to a significant extent by renal enzymes and not given with cilastatin. It has less potential to cause seizures and is less nephrotoxic than imipenem.

iii. *Ertapenem:* It is similar to meropenem in most aspects except that it is not active against *P. aeruginosa* and *Acinetobacter*. Its in vitro activity against Enterobacteriaceae carrying plasmid- or chromosomal-mediated beta-lactamases, including AmpC- and extended-spectrum beta-lactamases, is especially clinically significant.

iv. *Doripenem:* The supposed advantage of doripenem over other carbapenems is its potent activity against pseudomonas. Data from 6 phase 3 multinational doripenem clinical trials on Ciprofloxacin-Resistant Enterobacteriaceae (CIPRE) and Extended-Spectrum Beta-Lactamases (ESBL) were evaluated.[20] Doripenem and meropenem were more potent than other drugs.

4. Monobactams

Aztreonam: Its mechanism is similar to that of penicillins. The important feature of aztreonam is its resistance to most beta-lactamases. It has activity only against aerobic gram-negative bacteria like *E. coli*, *Klebsiella*, *Proteus*, *Providencia*, *Salmonella*, *Serratia*, *Shigella* and *Yersinia spp.* It has some activity against *P. aeruginosa* and *H. influenzae.*

Its major indications are serious infections caused by gram-negative organisms and is a useful alternative to aminoglycosides and third-generation cephalosporins. It is used in lower respiratory tract infections, including the pseudomonal infections in patients with cystic fibrosis, meningitis and sepsis. Use with an aminoglycoside is of benefit in serious *P. aeruginosa* infections.

It shows little cross-reactivity with penicillins and cephalosporins, with the exception of ceftazidime. Caution should be exercised in patients receiving anticoagulants as prothrombin time may be increased.

5. Beta-lactamase Inhibitors

Clavulanate, sulbactam and tazobactam are beta-lactamase inhibitors. When given in combination with beta-lactams, they inhibit plasmid-mediated beta-lactamases. Clavulanate is a suicide inhibitor of beta-lactamases produced by both gram-positive and gram-negative organisms. Since it is available as both oral and parenteral preparations, it has been combined with amoxicillin and ticarcillin to improve their antimicrobial spectra. Amoxicillin-clavulanic acid combination extends the spectrum of amoxicillin to beta-lactamase-producing strains of staphylococci and *H. influenzae.* Similarly, the antimicrobial spectrum of ticarcillin-clavulanic acid includes gram-negative bacilli and *S. aureus*.

Sulbactam is another beta-lactamase inhibitor available both as oral and parenteral preparation. Used with ampicillin, it improves the antimicrobial spectrum of ampicillin akin to that of amoxicillin. Tazobactam is available only for pareneteral administration. It is not effective against chromosomally mediated beta-lactamases. Though it is coadministered with piperacillin, the effectiveness of the combination against *P. aeruginosa* is doubtful. When given in combination, the dose of piperacillin gets reduced.

6. Macrolides

Erythromycin, the prototype of macrolides is obtained from *Streptomyces erythreus*. Clarithromycin and azithromycin are semisynthetic derivatives of erythromycin. These agents are largely bacteriostatic (may be bactericidal at high concentrations) and inhibit the growth of microorganisms by binding to the 50 S ribosomal subunit of sensitive microorganisms. They inhibit the translocation step in the peptide synthesis process wherein the newly formed peptidyl t-RNA moves from donor to acceptor site. Agents in this class also demonstrate postantibiotic effect where the effect persists after the antibiotic is removed from the system.

i. *Erythromycin:* The antimicrobial spectrum of erythromycin includes both gram-positive and certain gram-negative organisms. It is effective against pneumococci, streptococci, staphylococci and corynebacteria. Certain atypical microorganisms such as mycoplasma, legionella, *Chlamydia trachomatis, Chlamydophila psittaci, Chlamydophila* *pneumoniae, M. kansasii* and *Mycobacterium scrofulaceum* are also susceptible. Resistance has been seen in penicillin resistant *S. pneumoniae and* mycoplasma. Cross resistance is seen with other groups of these agents.

Erythromycin without an enteric coating is destroyed in the stomach. Erythromycin stearate, ethylsuccinate and estolate provide the requisite enteric coating and the latter is best able to resist destruction in the stomach. Absorption of erythromycin ethylsuccinate and estolate is not affected by the presence of food. Erythromycin gluceptate and lactobionate are available for intravenous administration. Only about 5% of the orally administered drug is excreted in the urine and dose adjustment is not required if the renal functions are compromised.

For pulmonary infections, the indications of erythromycin include acute tracheobronchitis, acute exacerbations of chronic bronchitis with or without complications, and for empirical antimicrobial therapy for pneumonia in previously healthy, ambulatory patients (pneumococcus, *Mycoplasma pneumoniae* being the usual causative organisms). It is also used for the elderly (*Pneumococcus, Klebsiella, S. aureus*, *H. influenzae* being the most likely causative organisms), empirical therapy of pneumonia in pediatric patients of one to three months of age (Chlamydia, ureaplasma, *Pneumocystis carinii* being potentially causative) and also for empirical therapy of pneumonia in children of more than 6 years of age (in whom pneumococcus and mycoplasma may be causative). Erythromycin is used in *Legionella* infections, and respiratory-tract infections such as bronchitis and pneumonia (mycoplasmal and other atypical pneumonias as well as streptococcal). It may be used as part of a multi-drug regimen for the treatment of inhalational anthrax. It is also used in the prevention of diphtheria in non-immune patients and of pertussis in non- or partially immune patients. It may be used as an alternative for actinomycosis for patients who are allergic to penicillin. It is also used as an alternative to the tetracyclines in patients with C*hlamydia pneumoni*a.

The adverse effects include gastrointestinal disturbances such as nausea, vomiting and diarrhea. Acute cholestatic hepatitis occurs most commonly with the estolate salt. This is a hypersensitivity reaction, which usually occurs 10 to 20 days after treatment and is characterized by nausea, vomiting, diarrhea and abdominal cramps. The condition recurs on the readministration of the drug. Reversible sensorineural deafness has been reported with its use. Prolongation of QT interval is known to occur with its administration. Erythromycin may aggravate myasthenia gravis. It inhibits cytochrome P450 enzyme and can lead to the elevated levels of theophylline, oral anticoagulants, cyclosporine and methylprednisolone. It may lead to the elevation of digoxin levels by the inhibition of gastrointestinal and renal P-glycoproteins.

ii. *Clarithromycin:* Clarithromycin is slightly more potent than erythromycin against the sensitive strains of streptococci and staphylococci, and has modest activity against *H. influenzae* and *Neisseria gonorrhoeae.* Clarithromycin has good activity against *M. catarrhalis, Chlamydia spp., Legionella pneumophila, Borrelia burgdorferi, Mycoplasma pneumoniae* and *Helicobacter pylori.* It is more active than erythromycin for Mycobacterium Avium Complex.

The oral absorption of clarithromycin is good. However, it undergoes extensive first pass metabolism. The extended release form is usually given with food to improve its bioavailability. The drug is metabolized in the liver to an active metabolite, 20% to 40% of the drug is excreted unchanged in the urine. Dosage adjustment is not needed in hepatic or renal impairment. Clarithromycin exhibits non-linear pharmacokinetics.

The gastrointestinal symptoms are lesser than that of erythromycin. Prolongation of QT interval has been reported rarely with its use. Isolated cases of corneal opacities, progressive cholestatic jaundice have been reported with its use. It inhibits CYP3A4 and has drug interactions similar to that seen with erythromycin. Concomitant use with theophylline, zidovudine, digoxin, statins, colchicine and carbamazepine may lead to the increase of serum levels and toxicity of these drugs. With verapamil, it may lead to hypotension, bradyarrhythmias and lactic acidosis, it may potentiate the effects of the oral anticoagulants. Inducers of the CYP3A4 (efavirenz, nevirapine, rifampicin, rifabutin and rifapentine) may increase clarithromycin metabolism and thus lower its plasma levels. Both clarithromycin and itraconazole (and also saquinavir) are CYP substrates and increase the plasma levels of each other if used together. QT prolongation leading to torsades de pointes has been reported with its concurrent use with other QT prolonging drugs.

iii. *Azithromycin:* Azithromycin generally is less active than erythromycin against gram-positive organisms and slightly more active than either erythromycin or clarithromycin against *H. influenzae* and *Campylobacter spp*. Azithromycin is very active against *Moraxella catarrhalis, Chlamydia spp.*, *M. pneumonia and L. pneumophila.* It is also active against some atypical mycobacteria. Its adverse effects and drug interactions are similar to clarithromycin.

iv. *Roxithromycin:* It is similar to azithromycin in the terms of spectrum and indications. The dose may need to be reduced in patients with hepatic or renal impairment. Gastrointestinal side effects are less as compared to erythromycin.

v. *Telithromycin:* It is actually a ketolide, obtained from the structural modification of macrolide structure. Addition of keto group confers its properties, which make it less prone to resistance. It is indicated for mild to moderate community-acquired pneumonia due to *S. pneumoniae*, including multi-drug resistant, *H. influenzae*, *M. catarrhalis*, *C. pneumoniae* or *M. pneumoniae*.

Mild gastrointestinal disturbances occur commonly. Severe liver injury leading to acute hepatic failure and even death has been reported. Visual disturbances (such as blurred vision, difficulty in focusing and diplopia) and transient loss of consciousness have been reported because of which patients should be advised to be careful while driving or operating machinery. It should not be given to patients with myasthenia gravis as it may lead to disease exacerbation. It may cause clinically significant QT prolongation. *Clostridium difficile* Associated Diarrhea (CDAD), which may range in severity from mild diarrhea to fatal colitis, has been reported.

7. Quinolones and Fluoroquinolones

Quinolones are derivatives of nalidixic acid. A major disadvantage with nalidixic acid and other quinolones (cinoxacin and oxolinic acid—no longer used) was the fact that they did not achieve sufficient concentration in the blood and tissues and were only suitable for very few conditions, like urinary tract infections. Fluorination of nalidixic acid has led to the development of compounds, which can achieve sufficient concentrations in the blood and tissues and have wider antibacterial spectrum.

Mechanism of action: Fluoroquinolones inhibit two enzymes, Topoisomerase II (DNA gyrase) and Topoisomerase IV. DNA gyrase condenses the large DNA strands into the cell by introducing supercoils into the DNA. During this supercoiling process, both DNA strands are cleaved by DNA gyrase, forming a "quinolone binding pocket."[21] Two quinolone molecules enter this pocket and inhibit further supercoiling. This creates gaps in the DNA strands activating exonucleases (DNA repair enzymes) leading to irreversible DNA damage and cell death. The function of Topoisomerase IV is not well-understood, but appears to be involved in the separation of the DNA daughter chains. Quinolones inhibit DNA gyrase in gram-negative organisms and Topoisomerase IV in gram-positive bacteria.

Pharmacokinetics: Fluoroquinolones in general are drugs with excellent oral bioavailability and have low-plasma protein binding of about 30% (Table 13.1). They readily and rapidly penetrate the body tissues, achieving tissue and fluid concentrations that are generally higher than those in plasma. Peak serum concentrations occur within one to two hours of oral doses. Longer half-lives (10 hours) of some quinolones (trovafloxacin, grepafloxacin, moxifloxacin) permit once-daily dosing. Although levofloxacin has a short half-life, it is used once daily. Fluoroquinolones are eliminated by both renal and nonrenal mechanisms (Table 13.1).

TABLE 13.1: Pharmacokinetic features of fluoroquinolones

Drug	*Half-life (hours)*	*Bioavailability (%)*	*With respect to food*	*Route of elimination*	*Dose adjustment*
Ciprofloxacin	3-5	60-80	Empty stomach	Renal > hepatic	Cr clearance < 30 ml/min
Ofloxacin	4 - 5	~ 100	No effect	Renal	Cr clearance < 50 ml/min
Gatifloxacin	7 - 14	95	No effect	Renal	Renal dysfunction
Gemifloxacin	7	70	No effect	Renal > hepatic	Cr clearance < 40 ml/min
Levofloxacin	7	90	No effect	Renal	Cr clearance < 50 ml/min
Moxifloxacin	13	99	No effect	Hepatic > Renal	Cirrhosis
Lomefloxacin	8	>90	Empty stomach	Renal	Renal dysfunction
Pefloxacin	8 -13	>70	Empty stomach	Hepatic	Hepatic dysfunction
Grepafloxacin	12	70	No effect	Hepatic	Hepatic dysfunction

TABLE 13.2: Classification and spectrum of quinolones[1]

Classification	*Drugs*	*Antimicrobial spectrum*
First generation	Nalidixic acid, Cinoxacin	Gram-negative organisms (but not Pseudomonas)
Second generation	Norfloxacin, Lomefloxacin, Enoxacin, Ofloxacin, Ciprofloxacin	Gram-negative organisms (including Pseudomonas), some gram-positive organisms (*Staphylococcus aureus*, but not *Streptococcus pneumoniae*) and some atypical pathogens
Third generation	Levofloxacin,Sparfloxacin, Gatifloxacin, Moxifloxacin	Same as of second-generation agents plus expanded gram-positive coverage (penicillin-sensitive and penicillin-resistant *S. pneumoniae*) and expanded activity against atypical pathogens
Fourth generation	Trovafloxacin	Same as of third-generation agents plus broad anaerobic coverage

Spectrum, pulmonary indications and dosage: Till date four generations of quinolones have been developed (Tables 13.2 and 13.3).[22] The first-generation compounds have activity against both gram-negative and gram-positive organisms. However, compared to quinolones of subsequent generations, the activity is not very potent. The second-generation agents have good activity against gram-negative organisms and moderately good activity against gram-positive organisms. While good activity against pseudomonas (ciprofloxacin in particular) is an advantage, methicillin-resistant staphylococci and streptococcal infections may not respond to this group, except to levofloxacin, which may have superior efficacy.

Most of the newer fluoroquinolones are effective in sinusitis, acute bacterial exacerbations of chronic bronchitis, and for presumptive therapy for pneumonia in adults with chronic bronchitis or alcoholism. Some of them are also indicated in community- and hospital-acquired pneumonia. Mild to moderate respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis also respond to oral fluoroquinolone therapy. Unlabeled respiratory indications of fluoroquinolones include pulmonary tuberculosis, anthrax, Legionnaires' disease and community-acquired pneumonia in children.

Adverse drug reactions and drug interactions: Fluoroquinolones are relatively safe drugs, the adverse effects are generally mild and rarely need discontinuation of therapy. The overall incidence of adverse reactions with fluoroquinolones is low (approximately 6% to 7%), the most common are gastrointestinal (mild nausea, vomiting and/or abdominal discomfort) reported in 3 to 17% of patients. Mild headache and dizziness have been reported in up to 11% of patients.

A typical, but rare adverse effect seen with these drugs is the photosensitivity or phototoxicity reaction, which can be moderate to severe. It may include exaggerated sunburn reactions (burning, erythema, exudation, vesicles, blistering, edema) on areas exposed to sun or artificial Ultraviolet (UV) light. Relative potential of the various fluoroquinolones to cause photosensitivity/phototoxicity is unclear. Patients should be advised to avoid unnecessary or excessive exposure to sunlight and artificial UV light, cover the skin with clothing or use sunscreen. The drug should be discontinued if this adverse reaction occurs.

The effect of quinolones on cartilage has been a matter of debate, precluding their use in immature animals. Ciprofloxacin, norfloxacin and nalidixic acid have been given safely in children with cystic fibrosis with few reports of reversible joint symptoms. Achilles tendon rupture or tendinitis had occurred with their use prompting US Food and Drug Administration to add a black box warning with the use of all fluoroquinolones. Leukopenia, eosinophilia and mild elevations in serum transaminases occur rarely. As with most antimicrobials, *Clostridium difficile*-associated diarrhea and colitis (antibiotic-associated diarrhea or pseudomembranous colitis) have been reported in patients receiving fluoroquinolones.

Rarely, serious and occasionally fatal hypersensitivity and/or anaphylactic reactions have occurred usually after multiple doses. Sometimes there is concomitant cardiovascular collapse, loss of consciousness, tingling, edema (pharyngeal or facial), dyspnea, urticaria or pruritus. Fever, rash or severe dermatologic reactions (toxic epidermal necrolysis, Stevens-Johnson syndrome), vasculitis, arthralgia, myalgia, serum sickness, allergic pneumonitis, interstitial nephritis, acute renal insufficiency or failure, hepatitis, jaundice, acute hepatic necrosis or failure, anemia (including hemolytic and aplastic), thrombocytopenia (including thrombotic thrombocytopenic purpura), leukopenia, agranulocytosis, and pancytopenia have all been reported. They require

TABLE 13.3: Approved respiratory indications of fluoroquinolones

Drug	*Indication*	*Dosage*	*Route*
Ciprofloxacin	Ear, nose, and throat infections (including otitis externa, otitis media, and sinusitis)	250 to 750 mg BD. IV dose is 200-400 mg BD	PO, IV
	Lower respiratory tract infections (including pseudomonal infections in cystic fibrosis, but excluding infections due to *S. pneumoniae)*	In cystic fibrosis, 40 mg/kg/day PO	
	Respiratory infections in cystic fibrosis patients	div q12h	
	Anthrax	In anthrax, : 400 mg IV q12h or 500 mg PO q12h	
Lomefloxacin	Acute exacerbation of chronic bronchitis caused by *Haemophilus influenzae* or *Moraxella catarrhalis*	400 mg OD for 10 days	PO
Gemifloxacin	Acute exacerbation of chronic bronchitis caused by *S. pneumoniae, H. influenzae, Haemophilus parainfluenzae,* or *M. catarrhalis*	320 mg OD for *5 days* in the treatment of acute exacerbation of chronic bronchitis	PO
	Mild-to-moderate community acquired pneumonia caused by *S. pneumoniae* (including penicillin-resistant strains), *H. influenzae, M. catarrhalis, Mycoplasma pneumoniae, Chlamydia pneumoniae,* or *Klebsiella pneumoniae*	320 mg OD for 7 days in the treatment of community-acquired pneumonia	
Levofloxacin	Acute mild to moderate sinusitis due to *S. pneumoniae, H. influenzae,* or *M. catarrhalis*	For sinusitis, 500 or 750 mg OD for 5 days	PO, IV
	Mild to moderate acute exacerbation of chronic bronchitis due to *S. aureus, S. pneumoniae, H. influenzae, H. parainfluenzae* or *M. catarrhalis*	For acute exacerbation of chronic bronchitis, 500 mg OD for 7 days or 750 mg OD for 5 days	
	Mild, moderate or severe community-acquired pneumonia caused by *S. aureus, S. pneumoniae* (including penicillin-resistant strains), *H. influenzae, M. catarrhalis, M. pneumoniae, C. pneumoniae, Legionella pneumophila* or *K. pneumoniae.*	For community acquired pneumonia, 500 mg OD for 7–14 days or 750 mg OD for 5 days	
	Nosocomial pneumonia due to methicillin-suscpetible *S. aureus, P. aeruginosa, Serratia marcescens, E. coli, K. pneumoniae, H. influenzae* or *S. pneumoniae*	For nosocomial pneumonia, 750 mg OD for 7–14 days	
Moxifloxacin	Acute bacterial sinusitis caused by *S. pneumoniae*, *H. influenzae* or *M. catarrhalis*	For sinusitis 400 mg OD for 10 days.	PO, IV
	Acute exacerbations of chronic bronchitis due to *S. pneumoniae*, *H. influenzae*, *H. parainfluenzae*, *K. pneumoniae*, *S. aureus* (methicillin-susceptible strains), or *M. catarrhalis*	Acute exacerbations of chronic bronchitis 400 mg OD for 5 days	
	Community-acquired pneumonia due to S. *pneumoniae* (including multidrug-resistant strains), *S. aureus* (oxacillin-susceptible strains), *K. pneumoniae*, *H. influenzae*, *M. pneumoniae*, or *M. catarrhalis*.	For community-acquired pneumonia (CAP), 400 OD for 7–14 days.	

BD: twice daily; OD: once daily; PO: orally; IV: intravenous immediate termination of therapy. QT_c prolongation has been observed with sparfloxacin (withdrawn in some countries) and to a lesser extent with gatifloxacin and moxifloxacin warranting their use with care in patients on class III (*amiodarone*) and class IA (*quinidine, procainamide*) antiarrhythmics.

In conjunction with theophylline or Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), hallucinations, delirium and seizures may rarely occur. Ciprofloxacin and pefloxacin inhibit the metabolism of theophylline, and toxicity from elevated concentrations of methylxanthine may occur. Concomitant use of corticosteroids increases the risk of severe tendon disorders (tendinitis, tendon rupture), especially in geriatric patients of older than 60 years of age. Antacids, sucralfate, metal preparations and multivitamins should be taken at least two hours prior or two hours after the administration of some of the oral fluoroquinolones (like levofloxacin) and four to eight hours for moxifloxacin. Quinolones may enhance the effects of warfarin, therefore, it is advisable to closely monitor coagulation parameters.

8. Aminoglycosides

Aminoglycosides are bactericidal drugs and their importance lies in their ability to synergize with the action of penicillins especially against enterococci and streptococci. Agents in this class are derived from either *Streptomyces* (framycetin, kanamycin, neomycin, paromomycin, streptomycin and tobramycin) or the genus *Micromonospora* [gentamicin (which is why it is not spelled *gentamycin*) and sisomicin]. They act by several mechanisms, but mainly through the inhibition of 30 S and 50 S portions of bacterial ribosomes. They are also known to disrupt the integrity of bacterial cell membrane.

Spectrum: The antimicrobial spectrum of aminoglycosides includes aerobic gram-negative bacilli. As mentioned earlier, their action may be extended to gram-positive bacteria when given with penicillins. The most clinically important mechanism of resistance is their inactivation by aminoglycoside modifying enzymes acetyltransferases, adenyltransferases or phosphotransferases. The other mechanisms include (i) decreased permeability of the antimicrobial into the cells because of alteration in their transport system, inadequate membrane potential, or modification in the lipopolysaccharides, and (ii) mutations in chromosomal genes encoding ribosomes leading to alteration in their targets. Cross resistance to other aminoglycosides may occur, but is less with amikacin.

Pharmacokinetics: This group of antibiotics is not absorbed orally and needs to be administered either via intramuscular or as intravenous infusion. Aminoglycosides exhibit concentration dependent kinetics and have considerable post-antibiotic effect. These two properties make it prudent to administer aminoglycosides as a single large dose rather than multiple small doses. With once a day regimen, the propensity for toxicity is also reduced once daily dosing allows for longer periods for which the drug remains below the threshold concentration. Additionally, once a day administration has the advantage of enabling treatment in an outpatient setting.

The polar nature of these compounds does not allow intracellular penetration, thereby considerably reducing the volume of distribution. Since aminoglycosides are largely eliminated renally, the dose has to be adjusted in accordance with creatinine clearance.

Therapeutic drug monitoring may be required with their use. The doses are adjusted so as to achieve a target concentration of less than 1 mcg/ml between 18 to 24 hours after the dose administration. Obtaining blood sample eight hours after drug administration will enable dose adjustment to achieve target concentration at 18 hours. When they are administered in multiple dose regimens, both peak and trough concentrations need to be measured.

For respiratory tract infections there are a few indications like infections due to gram-positive organisms, such as staphylococci, streptococci or pneumococci, where these antibiotics must be used. But they should be used in combination with penicillins. They are primarily indicated for infections (including serious infections of the respiratory tract) caused by gram-negative bacteria, including Pseudomonas, *E. coli*, Proteus, Providencia, *Klebsiella,* Enterobacter, Serratia and Acinetobacter. In spite of a large number of adverse effects associated with their use, they remain drugs of choice in many serious infections like septicemia, bacterial endocarditis and other serious infections caused by gram-negative bacilli.

i. *Gentamicin:* It is used in many severe systemic infections caused by susceptible organisms, including pneumonia, septicemia, endocarditis, cystic fibrosis, plague, meningitis, infections in immunocompromised patients and patients admitted in intensive care units. It is seldom used alone and is commonly prescribed with penicillins for streptococcal and enterococcal infections, with antipseudomonal beta-lactams for Pseudomonas, and with metronidazole (clindamycin) for mixed aerobic-anaerobic infections.

ii. *Tobramycin:* It is similar to gentamicin, but has been specifically used in pseudomonal infections.

iii. *Kanamycin:* It is also similar to gentamicin. Development of resistance is a bigger problem with kanamycin as compared to other aminoglycosides, which has led to a decline in its use.

iv. *Amikacin:* Its indications are similar to those of gentamicin except that should be reserved for the treatment of gentamicin- and tobramycin-resistant severe infections. It is also useful in nontuberculous mycobacterial infections. It is also used in combination with other antibiotics like gentamicin.

v. *Netilmicin:* It is similar to amikacin and can be used as its alternative. It was suggested that it is less nephrotoxic and ototoxic than other aminoglycosides. This has not been substantiated in all studies.

vi. *Streptomycin:* It is mainly used as an antitubercular drug and is covered elsewhere.

Adverse Effects of Aminoglycosides

Ototoxicity and nephrotoxicity are the major limitations. Ototoxicity manifests as vestibular disturbance and/or auditory dysfunction. The irreversibility of ototoxicity makes it a cause of concern. Mild ototoxicity may be seen in up to 25% patients, but overt ototoxicity occurs in 2% to 10%. A high pitched tinnitus is the first sign of cochlear toxicity. If the drug is not discontinued, permanent auditory dysfunction may occur. Vestibular toxicity is more difficult to diagnose and headache may precede vestibular toxicity. This progresses onto loss of coordination, mental past pointing and positive Romberg’s test. Predisposing factors include extremes of age, higher dose/duration of use, raised peak and trough levels, and concurrent use of other ototoxic drugs. Aminoglycosides constitute the single most common cause of bilateral vestibulopathy, accounting for 15% to 50% of all cases.[23]

Nephrotoxicity caused due to the accumulation of drugs in proximal convoluted tubule is seen in 8% to 26% patients, its incidence is similar with different aminoglycosides. Unlike ototoxicity, nephrotoxicity is almost always reversible if treatment is promptly discontinued. Typical picture is that of nonoliguric renal failure; elevation of serum creatinine; albuminuria; presence of red cells, white cells and casts; and development of hypoosmolar urine after several days of therapy. Azotemia and oliguria have also been reported. Predisposing factors include high dose and long duration of drug administration, high peak and trough levels, extremes of age, compromised renal function, dehydration and concurrent use of other nephrotoxic drugs.

The third important adverse effect of aminoglycosides is neuromuscular-blocking action leading to respiratory depression and muscle paralysis. Other adverse reactions (seen rarely) include rash, fever, headache, anaphylaxis, nausea and vomiting, tremor, arthralgia, hypotension, blood dyscrasias, purpura, stomatitis, liver dysfunction, peripheral neuropathy, meningeal irritation encephalopathy, confusion, lethargy, hallucinations and convulsions. Liposomal formulations of some aminoglycosides like gentamicin and amikacin are being developed with the hope of reducing adverse effects.

9. Tetracyclines

Tetracyclines are protein synthesis inhibitors. They bind to the 30 S subunit of bacterial ribosome blocking the binding of aminoacyl-tRNA to the acceptor site on the m-RNA ribosome complex. They are bacteriostatic broad spectrum antibiotics with susceptibility extending to gram-positive, gram-negative, aerobes, anaerobes, rickettsia and mycoplasma. Resistance to the tetracyclines is common, is mediated by plasmids preventing drug accumulation within the cell by decreasing active transport of the drug or by increasing efflux.

Tetracyclines differ amongst each other mainly for pharmacokinetic parameters (Table 13.4). Antimicrobial spectrum of different tetracylines is largely the same. However, organisms showing resistance to certain tetracyclines may still be susceptible to doxycycline, minocycline and tigecycline, the new generation tetracyclines.

Indications and Dosage: Tetracyclines are broad-spectrum antimicrobials active in rickettsial infections, pharyngitis, sinusitis, or pneumonia due to *C. pneumoniae* and by *M. pneumoniae* (Table 13.5). They can also be used in community-acquired bacterial pneumonia caused by penicillin-susceptible *S. pneumoniae*, including in patients with associated bacteremia, beta-lactamase negative *H. influenzae* and *L. pneumophila.* They are also used (along with streptomycin) in brucellosis and plague. They are also effective in anthrax and chronic bronchitis.

Doxycycline, minocycline, tetracycline hydrochloride are commonly used for acute respiratory exacerbations of chronic bronchitis .[24] Doxycycline is also used for empirical therapy of pneumonia in previously healthy patients with no history of antibiotic intake. Though not approved for this indication, tigecycline has been shown to be as effective as levofloxacin in hospitalized adult patients with community-acquired pneumonia.

Adverse effects: The most common gastrointestinal (nausea, vomiting and diarrhea) adverse effects of

TABLE 13.4: Important pharmacokinetic aspects of tetracyclines

Tetracycline	*Oral bioavailability*	*Half-life*	*Duration of action*	*Metabolism and elimination*
Chlortetracycline	30%		Short acting	Mainly eliminated by kidney, though undergoes enterohepatic recirculation
Oxycline	60-80%	6-12 hrs	Short acting	Mainly eliminated by kidney, though undergoes enterohepatic recirculation
Demeclocycline	60-80%	16 hrs	Intermediate acting	Mainly eliminated by kidney, though undergoes enterohepatic recirculation. Photosensitivity reactions are common. Known to cause nephrogenic diabetes insipidus
Tetracycline	60-80%	6-12 hrs	Short acting	Mainly eliminated by kidneys, though undergoes enterohepatic recirculation
Doxycycline	95%	16-18 hrs	Long acting	Mainly eliminated by kidneys
Minocycline	100%	16-18 hrs	Long acting	Significantly metabolized by the liver. It is also retained in fatty tissues
Tigecycline	Not given orally due to poor oral bio-availability	36 hrs	Long acting	59% eliminated by biliary/fecal excretion, and 33% excreted in urine

TABLE 13.5: Doses and some features of tetracyclines

Drug	*Dose*	*Remarks*
Tetracycline	250 or 500 mg four times a day (maximum 4 g/day) orally or by slow IV infusion or intramuscularly	1 hour before or 2 hours after meals Avoid in patients with renal impairment
Demeclocycline	600 mg/day in 2 or 4 divided doses. Preferably for atypical pneumonia, 900 mg/day in 3 divided doses	1 hour before or 2 hours after meals. In patients with liver disease, maximum dose is 1 g/day
Doxycycline	200 mg on day 1, followed by 100 mg/day orally or IV. In severe infections 200 mg/d throughout	May be used in patients with renal impairment.
Minocycline	200 mg loading dose followed by 200 mg/day in 2 divided doses orally or by slow IV infusion	More active against *S. aureus*, Streptococci, *Acinetobacter*, *Bacteroides*, *Hemophilus*, and some mycobacteria
Tigecycline	100 mg loading dose followed by 50 mg twice daily by IV infusion over 30 to 60 minutes	Effective against tetracycline-resistant organisms

tetracycline occur because of mucosal irritation. Esophageal ulceration can occur, therefore, oral preparations should be taken with sufficient water, in sitting or supine position, and a few hours before bedtime.

Glossitis, stomatitis, dysphagia, oral candidiasis, vulvovaginitis may occur due to overgrowth with *Candida albicans*. Antibiotic-associated diarrhea can occur as with most antimicrobials. Doxycycline may be less prone to cause GI adverse effects because of better absorption. Other serious complications of tetracycline therapy may include side effects such as, renal dysfunction, especially in patients with preexisting renal disease; increases in liver enzymes; rarely severe hepatotoxicity; and pancreatitis. They are deposited in both milk teeth and permanent teeth leading to permanent discoloration and enamel hypoplasia. Tetracyclines are also deposited in calcifying areas in bone and nails and may interfere with bone growth.

Abnormal pigmentation of skin, conjunctiva, oral mucosa, tongue, and internal organs such as the thyroid has occurred rarely. Permanent discoloration of cornea has been reported in infants born to mothers given tetracycline in high doses during pregnancy. Intracranial hypertension with headache, dizziness, tinnitus, visual disturbances and papilledema have been reported. Transient myopia, muscle weakness in patients with myasthenia gravis, lupus exacerbation, hypersensitivity reactions, phototoxicity, and rarely agranulocytosis, aplastic anemia, hemolytic anemia, eosinophilia, neutropenia, and thrombocytopenia have been reported. They can also cause hypoprothrombinemia and reduction in serum-vitamin B concentrations. Outdated tetracyclines can cause Fanconi-type syndrome.

Drug interactions: The absorption of tetracyclines is reduced by antacids, iron, and milk and dairy products. Therefore it is advisable to have a gap of one to three hours in between. Nephrotoxicity and hepatotoxicity of tetracyclines may be increased by other nephrotoxic and hepatotoxic drugs, respectively. Concomitant use with retinoids may lead to an increased incidence of benign intracranial hypertension. Tetracyclines may decrease the efficacy of oral contraceptives. Bactericidal drugs like penicillins should not be used with tetracyclines (bacteriostatic).

10. Glycopeptides

They include vancomycin, teicoplanin, and others like telavancin, ramoplanin, decaplanin. Their mechanism of action is the inhibition of cell wall synthesis by binding to d-Ala d-Ala terminus of nascent peptidoglycan inhibiting synthesis of peptidoglycan. This group of drugs should be reserved for serious, multidrug-resistant infections since resistance to these drugs is uncommon, and also because of their toxicity profile.

i. *Vancomycin:* It is active against *S. aureus, S. epidermidis* (including meticillin-resistant), *S. pneumoniae, S. pyogenes, Viridans streptococci, Enterococci, Clostridium, Actinomyces, Bacillus anthracis, Corynebacterium*, lactobacilli and *Listeria.* Like other beta-lactams, it is synergistic with the aminoglycosides. Resistance is plasmid-mediated and may be transferable to other gram-positive organisms; it has been seen in *Lactobacillus* and enterococci.

   Its major indication is serious gram-positive infections like methicillin-resistant staphylococcal infections (brain abscess, meningitis, sepsis), nosocomial pneumonia, neutropenic and immunocompromised patients when other beta-lactams cannot be used because of microbial resistance, adverse effects or hypersensitivity.

   It may cause histamine release leading to erythema, flushing, or rash over the face and upper torso (“red man syndrome”); rarely hypotension and shock may occur.

   Nephrotoxicity and ototoxicity are two other serious adverse effects, which are more likely to occur in patients with renal impairment or with high dose. Ototoxicity (may be irreversible) is more common in patients with preexisting hearing problems and with concomitant use of other ototoxic drugs. Tinnitus is usually the first sign of impending ototoxicity and warrants stoppage of treatment. Because of its irritant nature, thrombophlebitis can occur, but is rare if it is used diluted and infused slowly. Inhalational use has caused bronchoconstriction, which is treated with inhaled beta agonists.

ii. *Teicoplanin:* Its spectrum and resistance patterns are similar to vancomycin. Cross-resistance with vancomycin occurs, but may not be complete. It is not orally absorbed and is given parenterally. It is excreted by the kidneys with a half-life of about 60 hours. Incidence of “red man” syndrome is less. It is also less irritant and, therefore, incidence of thrombophlebitis is less.

iii. Dalbavancin and telavancin are two other glycopeptides under development. The former is characterized by a long half-life permitting once a week administration. Telavancin has activity against gram-positive bacteria and against strains with intermediate sensitivity to vancomycin. It has dual mechanism of action as it inhibits both cell wall and cell membrane.

11. Miscellaneous Antimicrobials

i. *Trimethoprim-Sulfamethoxazole:* The combination of trimethoprim and sulfamethoxazole is synergistic in action by the virtue of its action on two sequential steps in the synthesis of folic acid. Sulfamethoxazole inhibits the incorporation of Para Aminobenzoic Acid (PABA) into folic acid while trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate. Both of these steps are required in the synthesis of folic acid. The antimicrobial spectrum of the combination includes *Chlamydiae diphtheria, S. aureus, S. epidermidis, Streptococcus pyogenes, Klebsiella sp.*, pneumocystis and *Yersinia pseudotuberculosis*. Methicillin-resistant strains of *S. aureus* may be susceptible to trimethoprim-sulfamethoxazole. Widespread resistance is common in streptococci. Resistance has been commonly observed in both gram-positive and gram-negative organisms.

Indications and dosage: The combination is available as 80 mg trimethoprim and 400 mg sulfamethoxazole and as Double Strength (DS) tablets containing 160 mg trimethoprim and 800 mg sulfamethoxazole. For the treatment of acute exacerbations of chronic bronchitis (it is not first or even second choice) due to susceptible strains of *S. pneumoniae* or *H. influenzae,* it is used as one DS tablet twice daily for 10 to 14 days. The daily dose for treatment of *P. carinii* pneumonia is 15 to 20 mg/kg trimethoprim and 75 to 100 mg/kg sulfamethoxazole in equally divided doses every six hours for 14 to 21 days. For prophylaxis of *P. carinii*, the dose is one DS tablet once daily. Doses will need to be adjusted for creatinine clearance.

Adverse effects: Adverse effects are common, include gastrointestinal disturbances (nausea, vomiting, anorexia) and skin reactions (rash and urticaria). Blood dyscrasias may occur. Caution needs to be exercised in patients with hepatic or renal impairment. It is contraindicated in patients with megaloblastic anemia due to folate deficiency. Folate supplementation is required if the drug is given for a proloned period or when used in elderly patients with a tendency for folate deficiency. Rarely, fatal reactions like Stevens-Johnson syndrome, toxic epidermal necrolysis, fulminant hepatic necrosis, agranulocytosis, aplastic anemia, other blood dyscrasias, and hypersensitivity of the respiratory tract have occurred. Renal failure, interstitial nephritis, hyperkalemia, hyponatremia, aseptic meningitis, convulsions, peripheral neuritis, ataxia, vertigo, tinnitus, headache, hallucinations, depression, apathy, nervousness, arthralgias, myalgias, cough, shortness of breath, and pulmonary infiltrates have all been reported.

ii. *Chloramphenicol:* It is a broad-spectrum bacteriostatic antimicrobial effective against gram-positive and gram-negative bacteria, as well as several others that acts by binding to the 50 S subunit of the bacterial ribosome leading to the inhibition of protein synthesis. Its spectrum includes *H. influenzae*, *N. meningitidis*, *S. pneumoniae*, *S. pyogenes, Viridans streptococci, S. epidermidis, S. aureus* (not all strains), and streptococci such as *Str. pneumoniae*, *S. pyogenes*, *B. anthracis*, *C. diphtheriae*, *Peptococcus, Peptostreptococcus, Bordetella pertussis, Brucella abortus*, *Campylobacter*, *Legionella pneumophila* and *B. fragilis*.

Bone marrow depression is the most important and potentially fatal adverse effect. The depression is generally reversible, related to the dose. Rarely, (1 in 50,000) it is dose-independent and irreversible. "Grey baby syndrome" is typically seen in premature infants characterized by ashen color of skin, abdominal distension, vomiting and hypothermia, progressing as to development of cyanosis, disturbed breathing, circulatory collapse and death. Bleeding, hemolytic anemia (especially in G-6-PD deficiency), neuritis (including optic), encephalopathy, headache, and ototoxicity have all been seen with its use.

iii. *Linezolid:* The oxazolidinone *linezolid* has activity against gram-positive organisms, including the vancomycin-resistant enterococci and methicillin-resistant *S. aureus*. It is a bacteriostatic drug and acts by the inhibition of ribosomal proteins.

It is well-absorbed after oral administration. It is an alternative to vancomycin for community-acquired pneumonia due to methicillin-resistant *S. aureus* (MRSA) and for hospital-acquired pneumonia, where the possibility of MRSA infection exists. It is also used for infections of the respiratory tract, including those due to vancomycin-resistant enterococci and methicillin-resistant *S. aureus.* It has been also used in the treatment of nocardiosis.[25]

Lactic acidosis, convulsions, bullous skin eruptions, including Stevens-Johnson syndrome, peripheral neuropathy, optic neuropathy (leading to blindness), and reversible myelosuppression have been rarely reported. It should not be used in gram-negative infections; increased mortality in patients with gram-negative or mixed infections was seen in a trial comparing linezolid to vancomycin, oxacillin or dicloxacillin (21.5% vs 16%) leading to an FDA alert in 2007.[26] It is a reversible and nonselective inhibitor of enzyme Monoamine Oxidase (MAO) and, therefore, can interact with adrenergic and serotonergic drugs similar to antidepressant MAO inhibitors. Serotonin syndrome may be precipitated when linezolid is used with Selective Serotonin Reuptake Inhibitors (SSRIs). Marked increase in blood may be seen with dopamine or adrenaline, reduction in the doses of these pressor agents may be needed.

iv. *Streptogramins:* Quinupristin and dalfopristin are semisynthetic derivatives of pristinamycin I and II respectively, used in a ratio of 3:7. They act by inhibiting protein synthesis by binding to the 50 S ribosomal subunit. The action of quinupristin and dalfopristin is synergistic. The spectrum includes MRSA, multidrug-resistant *Staphylococcus aureus,* vancomycin-resistant *Enterococcus faecium* (but not *E. faecalis*), penicillin- and macrolide-resistant *Streptococcus pneumoniae,* and gram-negative bacteria (*Legionella pneumophila*, *Moraxella catarrhalis* and *Mycoplasma pneumoniae).*

They are not absorbed orally. They are rapidly metabolized, the main route of elimination is fecal (3/4th) and the rest is eliminated in urine with half-lives of about one hour. They are approved for use in Europe for the treatment of nosocomial pneumonia and infections caused by MRSA. They are also indicated for the treatment of serious infections caused by gram-positive organisms, as well as vancomycin-resistant *E. faecium.*

Liver enzyme elevation, myalgias and arthalgias, anemia, neutropenia, eosinophila and thrombocytopenia may occur. They inhibit CYP3A4 and can increase blood levels of drugs metabolized by these enzymes. They may cause QT interval prolongation when given with other drugs having actions (like astemizole, terfinadine and cisapride).

v. *Lincosamides:* Lincomycin and clindamycin are not related structurally to erythromycin and the other macrolide antibacterials, but have similar antimicrobial activity. They act at the same site on bacterial ribosome. The lincosamides have a potential for use as alternatives to penicillin, however, pseudomembranous colitis limits their use for this indication. Currently, they may be considered for the treatment of severe anaerobic infections.

vi. *Polymyxins*: This group includes polymyxin B and colistin (also known as polymyxin M). In 1962, Edgar and Dickinson wrote,*"Attempts to cure infections caused by Pseudomonas…are often unsuccessful. Many strains of the organism are resistant to almost all chemotherapeutic agents, and strains initially sensitive may become resistant during treatment."*This statement holds true even today and this group of agents have emerged as a "last resort" antimicrobials for gram-negative infections resistant to all existing drugs.

They replace the Ca^{++} and Mg^{++} ions on the LPS layer of gram-negative cell wall leading to permeability changes and cell death. They also have a unique antiendotoxin activity for which they have been utilized in gram-negative bacterial sepsis and endotoxin-mediated shock.

They are bactericidal against most gram-negative bacilli except *Proteus* spp and are particularly effective against *Ps aeruginosa. Acinetobacter, E coli, Enterobacter* and *Klebsiella, H influenzae, B pertussis, Salmonella, Shigella Serratia, Burkholderia, and Providencia* , and *B fragilis* are usually resistant. They are also not active against *Neisseria* spp., obligate anaerobes, and gram-positive bacteria.

Polymyxins are not absorbed from GIT, through mucous membranes, or intact or denuded skin. They do not cross blood-brain barrier, pleura, synovial fluid, or placenta. The half-life is 6 hours and is prolonged in renal impairment. They can be administered topically for skin, ear, and eye infections; orally for selective digestive tract decontamination (SDD); parenterally for systemic infections; intrathecally for meningitis and subconjunctivally for ocular infections.

The dose for polymyxin B is 15,000 - 25,000 u/kg/day (max 2 million u/day). 5 lac units should be dissolved in 500 mL of D5 and infused over 24 h or it can be given in two divided doses every day - infused over one hour. It is also given by aerosolization for gram-negative nosocomial pneumonia and respiratory failure requiring mechanical ventilation. For this purpose, 25000 u/kg/d divided into 4 doses as 0.5% solution in NS is administered.

It is important to note that polymyxin B should be stored at controlled room temperature 15° to 30°C before reconstitution but it should be protected from light for which it may be retained in carton until time of use. After reconstitution it must be stored under refrigeration, between 2° to 8°C and any unused portion should be discarded after 72 hours.

Colistin is administered parenterally as colistimethate, in doses of 6 mln u/day in 3 divided doses up to a maximum of 6 mln u/d. It can be given as direct intermittent injection over 3-5 min every 12 h or by continuous infusion. For the latter, ½ of total daily dose is given over 3-5 min and the remaining ½ of total daily dose is dissolved NS or DNS or 5% D or Ringer Lactate and administered by slow IV infusion, starting 1-2 h after the initial dose, over the next 22-23 h. Colistimethate infusion should be freshly prepared and used within 24 h.

The oral dose for colistin is 1.5-3 mln units tid; as inhalation it is used in doses of 1-2 mln units bid-tid.

The major dose-related toxicity of polymyxins is neurotoxicity and nephrotoxicity for which they were infrequently used until a few years back. They can also cause hypersensitivity reactions including those due to histamine release leading to bronchoconstriction and anaphylactoid symptoms. The neurotoxicity is seen in about 7% of patients with normal renal function and manifests as paresthesias, visual disturbances, dizziness, ataxia, confusion, or drowsiness. Neuromuscular blockade is a serious complication and can lead to respiratory paralysis and apnea for which the only treatment is artificial respiration. Nephrotoxicity is the major adverse effect and older literature quotes the incidence as about 20%. However, it is believed that for the newer more purified polymyxins the incidence may be less.

In conclusion, polymyxins should be reserved only for serious gram-negative infections by bacteria resistant to all currently available β-lactams, aminoglycosides, and fluoroquinolines. Although both polymyxin B and colistin are similar in most aspects, polymyxin B may be superior to colistin for MDR *P. aeruginosa*. Patients with abnormal RFT should receive lower doses.

Antiviral Drugs

Nusrat Shafiq, Samir Malhotra

INTRODUCTION

The development of antiviral drugs has lagged behind that of antibacterial drugs. Although the first antibacterial drugs became available in the 1930s, the discovery of the first antiviral compounds occurred some two decades later. The first antivirals in clinical use were idoxuridine for herpetic keratitis and methisazone for the prophylaxis of smallpox in contacts and the treatment of the infective complications of smallpox in the 1960s.[1]

Advancements in combinatorial chemistry, computer-assisted drug design and elucidation of microorganisms' genomes coupled with the increasing understanding of viral replication mechanisms have provided information on several novel targets for new drug development with the result that we have been able to discover, over the past few years, several new drugs that are effective, selective for viruses and spare the host cells. Many viral infections for which no treatment was available until a few years ago are now amenable to treatment, e.g. HIV, hepatitis C (HCV) and B (HBV) viruses, herpes viruses, papillomavirus and influenza. However, there still exist several viral infections that have no treatment, for instance, poliomyelitis, common cold, rabies, mumps, rubella and others.

There are several reasons for the inability to discover novel, safe and effective antiviral drugs. Viruses are obligate intracellular parasites that, on entry into their host, need metabolic processes of the host cell to replicate. Consequently, the antiviral drug should either be able to block entry of the virus into the host cells or exit or be able to kill the virus within the host cells, but do it without interfering with the functions of the host cells. Therefore, selective inhibitors of these viral processes that do not cause toxicity to the host cells are difficult to develop. Moreover, viruses constantly change their antigens leading to alterations in drug target enzymes that not only makes drug development difficult, but also leads to the emergence of drug resistant strains. Some general features of antiviral chemotherapy are outlined below (Table 14.1).

TABLE 14.1: General features of antiviral chemotherapy

- None of the antiviral drugs is virucidal; these drugs are only able to inhibit viral replication (virustatic). Therefore, if the immune system of the host is compromised, viruses start replicating once treatment is stopped leading to disease recurrence and drug-resistance.
- The antiviral drugs are not effective against latent viruses and need active replication of the viruses to be effective.
- Early initiation of antiviral drug treatment is crucial for effectively controlling the infection.
- For most viral infections multi-drug therapy is needed.
- The correlation of culture sensitivity testing with clinical use is weaker as compared to antibacterial drugs mainly for the reason that these tests are not standardized for antiviral agents. Moreover, the antiviral drugs lead to adverse effects because of insufficient selectivity, which may make it difficult to choose a drug even if virus is sensitive to it in the lab.
- Antiviral drugs are not substitutes to immunization for prophylaxis of viral infections.
- An important property of any antiviral drug is its ability to penetrate the infected cells to be effective.
- Because of the relative ineffectiveness of most antiviral drugs, the role of symptomatic, supportive treatment must not be ignored.

MECHANISM OF ACTION OF ANTIVIRAL DRUGS

The basic processes for viral replication include viral attachment to certain host cell surface receptors followed by viral entry into the cell.[2] The virus then uncoats its nucleic acid and starts to synthesize the regulatory proteins necessary for synthesis of new viral RNA or DNA. With the help of host metabolic machinery, the virus is now capable of synthesizing structural proteins needed for the maturation of new viral particles. These newly formed viruses then leave the host cell to infect more cells. Currently available antiviral drugs utilize these steps in the viral replication process.

Anti-Influenza Drugs

Influenza is an acute respiratory-tract infection caused by Orthomyxoviridae family of RNA viruses. Of the three types of known influenza viruses (A, B and C), type A is the most important as it causes most infections (including the outbreaks) whereas types B and C are less commonly implicated and lead to mild infections. “Bird flu” (first reported in 1997 in Hong Kong) is also a form of influenza (avian or H5N1 influenza), may cause severe illness and has high mortality rates. “Swine flu” (H1N1 and other strains like H1N2, H3N1, etc.), first reported in 1918, had its most recent outbreak in humans in 2009.

There are two main classes of antiviral drugs for influenza: M2 ion channel inhibitors (amantadine, rimantadine) and neuraminidase inhibitors (oseltamivir, zanamivir). None of them is effective against all the types of influenza; and none of them has been proven to be conclusively effective against serious influenza infections when the risk of development of complications is high.

M2 Ion Channel Inhibitors

Amantadine and rimantadine inhibit viral uncoating and may reduce viral assembly probably via hemagglutinin pathway by acting on influenza A virus M2 protein, which is a membrane protein and is basically an ion channel. Although primary drug resistance is seen in less than 2% of viruses, acquired resistance is much more common (1/3rd of cases).[3]

Both these drugs are used for prophylaxis, as well as for the treatment of influenza A virus infections. For prophylaxis, 200 mg/day in one or two divided doses in young adults is about 70% to 90% protective.[4] For treatment, 200 mg/day for five days of either drug is considered useful although it reduces the duration of fever and systemic complaints by just about one to two days. These drugs are also used in hepatitis C, Parkinsonism is an unrelated indication. They are ineffective against influenza B, or avian influenza H5N1 strain or the H1N1 swine flu.

The most common adverse effects are minor Gastrointestinal (GI) disturbances (loss of appetite, nausea) and Central Nervous System (CNS) symptoms (anxiety, lightheadedness, difficulty concentrating, insomnia, etc.). The latter are seen in up to 30% of patients on amantadine, but are less common with rimantadine.[5] Rarely, serious adverse effects like cardiac arrhythmias, delirium, hallucinations, seizures and coma may occur.

Neuraminidase Inhibitors

Neuraminidase enzyme is important for the release of virus from infected cells and neuraminidase inhibitors cause a conformational change in the active site of the enzyme leading to its inhibition. Resistance occurs in 5% to 15% of cases. Oseltamivir is given orally and is rapidly absorbed. Zanamivir is not absorbed after oral administration and is used by inhalation when about 15% is deposited in the lower respiratory tract and about 80% in the oropharynx.[6] The plasma half-life of oseltamivir carboxylate is 6–10 hours and that of zanamivir is 2.5–5 hours after inhalation (1.7 hours after IV). Both the drugs are predominantly eliminated unchanged in the urine.

Both the drugs are effective in prophylaxis and treatment of influenza A and B virus infections. For prophylaxis, oseltamivir is given orally 75 mg or zanamivir intranasally once daily. For treatment, oseltamivir 75 mg twice daily or zanamivir 10 mg twice daily for five days are effective in reducing the duration of disease (by one day) and may reduce the risk of complications. These drugs also have some efficacy against some strains of avian influenza and swine flu.

Oseltamivir causes GI irritation leading to nausea, abdominal discomfort and vomiting, but these symptoms are self-limiting even if treatment is continued. They are also decreased if drug is taken with food. Headache may also occur, but is uncommon. Zanamivir inhalation can cause wheezing and bronchospasm that leads to deterioration in lung function. Occasionally, deaths have been reported especially in patients with underlying lung disease.

Second generation long-acting neuraminidase inhibitors: Single-dose or once weekly treatment may offer several advantages like superior patient compliance and greater protection in a population. The first Long-Acting Neuraminidase Inhibitor (LANI), hence the name **laninamivir,** has recently completed phase 3 of clinical new drug development and may be marketed within a few years of publication in some countries. It has been shown to have efficacy similar to that of oseltamivir in patients with influenza A or B. In another study, it reduced the median time to illness alleviation in pediatric patients with oseltamivir-resistant influenza A virus.[7] Besides influenza A and B, it may also have activity against other influenza viruses.

In conclusion, there is some evidence to show that neuraminidase inhibitors may be superior to M2 ion channel inhibitors in the view of their lesser incidence of resistance, fewer adverse effects and greater efficacy against influenza B. Neuraminidase inhibitors may also be effective against strains resistant to M2 ion channel inhibitors. Combination regimens of amantadine, ribavirin and oseltamivir have been shown to be effective for viruses resistant to neuraminidase inhibitors. However, these findings are only experimental and adverse effect profile of such combinations would need consideration.[8]

Antiviral Drugs for Respiratory Syncytial Virus (RSV) Infection

RSV is an RNA virus of the Paramyxoviridae family that causes respiratory infections in all age groups, although infants and young children are more susceptible. RSV is an important cause of serious respiratory illness in Blood and Marrow Transplant (BMT) recipients. In some subsets of these immunocompromised patients, RSV upper respiratory illnesses frequently progress to fatal viral pneumonia. The management is primarily supportive. Ribavirin is the only approved specific antiviral drug for RSV and palivizumab is a recently approved humanized monoclonal antibody.

Ribavirin

It is a synthetic nucleoside analogue structurally related to guanine and acts by inhibiting viral nucleic acid synthesis. It is rapidly and extensively absorbed after oral administration. Aerosolized ribavirin achieves high concentrations in the respiratory tract, but is also absorbed systemically. It is not metabolized, gets stored in the tissues and is slowly eliminated by the kidneys with a half-life of about 300 hours. It is indicated for severe RSV bronchiolitis and is preferably given by aerosol. It is also active against influenza, parainfluenza, Severe Acute Respiratory Syndrome (SARS), measles, mumps, HIV, herpesviruses, adenoviruses and poxviruses. The most common adverse effects of oral ribavirin are flu-like symptoms and neuropsychiatric disturbances (anxiety, depression, insomnia and irritability). Bacterial infections, hemolytic anemia, leukopenia, thrombocytopenia, aplastic anemia and several other complications may also occur. When given by inhalation, it can cause lung function worsening, bacterial pneumonia, pneumothorax and hypotension.

Palivizumab

Produced by recombinant DNA technology, it is an antibody against an epitope in the A antigenic site of F protein of RSV. It was approved for use in infants with high risk for RSV infection. It effectively neutralizes a broad range of clinical isolates of RSV and may be several times more active than RSV-IGIV. Palivizumab is administered in a dose of 15 mg/kg IM once a month during the RSV season, which may occur predominantly between December to February in India. Given with ribavirin, palivizumab has shown improvement in response rate.[9] Side effects include erythema, pain, induration and bruising at the injection site. Vomiting, diarrhea and fever, and mild to moderate elevation of aspartate aminotransferase may also occur.

Antiherpesvirus Drugs

Two types of herpesviruses are common pathogens—Herpes Simplex Virus Type 1 (HSV-1) and HSV-2. HSV-1 leads to oral, esophageal, facial, dermatological or brain infections whereas HSV-2 leads to genital, rectal, dermatological or meningeal infections. The major drugs used in these infections are synthetic nucleoside analogues—**acyclovir, valacyclovir, ganciclovir, valganciclovir, famciclovir** and **penciclovir,** and non-nucleoside pyrophosphate **foscarnet**. They inhibit viral DNA synthesis. Resistance is common and occurs by alterations in viral enzymes (thymidine kinase, DNA polymerase) involved in their mechanisms of action.

Nucleoside Analogues

Besides HSV infections, these drugs are also effective against Varicella-Zoster Virus (VZV) and prophylaxis of Cytomegalovirus (CMV) in immunocompromised patients, but they are ineffective against established CMV infections. Ganciclovir is also effective against HIV and hepatitis B virus. The dose of oral acyclovir is 200 mg five times daily or 400 mg three times daily for 7 to 10 days and that of valacyclovir is 1000 mg twice daily for 7 to 10 days. Intravenous acyclovir is used in doses of 5–20 mg/kg every eight hours. Ganciclovir is more effective against CMV and is used in doses of 5 mg/kg by IV infusion every 12 hours. Penciclovir is used topically as a 1% cream every two hours during waking hours for four days in the treatment of herpes labialis.[10] Famciclovir is given orally in doses of 250 mg three times daily, or 500 mg twice daily or 750 mg once daily.

These drugs can lead to nausea, diarrhea, rash, headache, renal insufficiency and neurotoxicity. Confusion and hallucinations can occur with high doses. Thrombocytopenia may also occur especially in immunocompromised patients.[11] Increased liver enzymes, hair loss, rash, Stevens-Johnson syndrome, toxic epidermal necrolysis and anaphylaxis have also been reported. Injection site reactions and even lead to tissue necrosis can occur with IV use. Hematological adverse effects are more common with ganciclovir.

Foscarnet

Besides herpesviruses it is also effective against CMV infections (pneumonia in bone marrow transplant patients and retinitis), including ganciclovir-resistant infections; HSV and VZV (including acyclovir-resistant); Epstein-Barr virus; VZV, HBV and HIV. The usual dose is 40–60 mg/kg infused over one hour every eight hours.

The most common serious dose-limiting toxicity is nephrotoxicity. It can also cause anemia, granulocytopenia and thrombocytopenia. It is a chelator of bivalent metal ions and lead to hypocalcemia with normal plasma levels of calcium. It can also cause injection site reactions, GI symptoms (nausea, vomiting, diarrhea), malaise, fatigue, fever, CNS disturbances (headache, tremors, dizziness, irritability, seizures, hallucinations and mood disorders), paresthesias, rash, increases in liver function tests, blood pressure, ECG abnormalities and pancreatitis.

Idoxuridine

It is a thymidine analog that inhibits replication of various DNA viruses, including (herpesviruses and poxviruses) mainly used for topical treatment of HSV keratitis. **Trifluridine** is a pyrimidine nucleoside that has activity against HSV 1 and 2, CMV, vaccinia, and some adenoviruses. It is used for primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2.

Antiviral Drugs for Severe Acute Respiratory Syndrome (SARS)

Severe acute respiratory syndrome is a respiratory illness caused by a newly identified coronavirus.[12] It is a serious disease and the mortality during the 2002–2003 outbreak was about 9.5%. Besides supportive treatment, corticosteroids, ribavirin, interferons, immunoglobulins and ritonavir-lopinavir have been tried, but convincing evidence for their efficacy is lacking.

Antifungal Drugs

J Whig, Bharti Mahajan, Rajesh Mahajan

INTRODUCTION

Systemic infections caused by fungi pose a major health problem in both the developed and the developing countries.[1] Fungi are recognized as fourth leading pathogen of nosocomial sepsis in USA.[2] The use of large number of antibiotics and the increasing number of immunocompromised patients in hospital care are the major factors responsible for the rising incidence of fungal infections.[3] Mortality among infected patients may be as high as 75 to 100%, presenting an enormous challenge for health care providers.[4]

There are estimated to be several hundred thousand species of fungi. However, only 150–200 were considered to be pathogenic for humans, which now are increasing at an alarming rate. The endemic fungal infections are acquired from the environmental sources, e.g. coccidioidomycosis, while the opportunistic mycoses are caused by the fungi, which are present in the normal human flora in an immunocompromised host, e.g. *Candida* (yeast) and *Aspergillus* (mould).[5]

All the fungal infections tend to be more aggressive in immunocompromised patients.[6] There is also an increasing incidence of infections with other moulds, including *Fusarium spp.*, *Scedosporium spp*, (Hyalohyphomycosis), and *Rhizopus spp.* (mucormycosis or zygomycosis).[7] It has intensified the search for newer, safer and more efficacious agents to combat serious fungal infections.[8] The number of agents available to treat fungal infections have increased by 30% since the year 2000.[9]

It is important to know the differences in the antifungal spectrum of activity, bioavailability, drug interactions and adverse effects of the various antifungal agents.[9] They are broadly classified into the following classes. These agents are mainly used for the systemic fungal infections.[10]

I. **Polyenes:** Amphotericin B (AMB), Nystatin
II. **Azoles**
   Imidazoles: Miconazole, Ketoconazole, Econazole
   Triazoles: Fluconazole, Itraconazole, Voriconazole, Posaconazole
III. **Antimetabolites/Nucleoside analogues:** Flucytosine
IV. **Echinocandins:** Caspofungin, Micafungin, Anidulafungin
V. **Miscellaneous:** Griseofulvin, Terbinafine and others.

Polyenes

Amphotericin B (AMB) and Nystatin are the currently available polyenes. They have an important role in antifungal management plans due to their broad spectrum of action against fungi and rarity of resistance.[11]

Amphotericin B (AMB)

It is an amphoteric polyene macrolide. It is almost insoluble in water, therefore, prepared as a colloidal suspension of AMB and sodium desoxycholate for Intravenous (IV) injection.[12] It binds to ergosterol present within the fungal cell wall membrane and leads to the formation of pores resulting in subsequent efflux of potassium and intracellular molecules causing fungal cell death (Fig. 15.1).[13]

Antifungal spectrum: AMB has useful activity against *Candida spp.*, Cryptococcus neoformans, Blastomyces dermatitidis, Histoplasma capsulatum, Sporothrix schenckii, Coccidioides immitis, Paracoccidioides brasiliensis, *Aspergillus spp.*, Penicillium marneffei and the agents of mucormycosis/zygomycosis.[14] Although conventional AMB (Fungizone in the form of micelles) remains the standard therapy for many invasive or life-threatening mycoses, the use of this drug is often limited by its toxicity, especially drug-induced renal impairment.[15] Consequently, it led to the development of Lipid Formulations of AMB (LFAmBs) - Amphotericin-B Lipid Complex (ABLC; in the form of ribbons), Liposomal Amphotericin-B (L-AMB) and Amphotericin-B colloidal dispersion (ABCD; in the form of disks). AMB is complexed to cholesteryl sulfate in all these preparations.[16]

Pharmacokinetics: AMB is poorly absorbed from the Gastrointestinal (GI) tract. Hence, oral AMB cannot be used for systemic fungal infections.[12] The drug is 90% bound to plasma proteins, largely β-lipoproteins. The penetration of AMB is very little into Cerebrospinal Fluid (CSF), vitreous humor and normal amniotic fluid.[14] Most of the drug is excreted unchanged by the kidney or the liver.[17] The half-life is approximately 15 days.[12]

There are striking differences in their plasma pharmacokinetics of lipid formulations. The L-AMB contains rigid, charged phospholipids and cholesterol to retain AMB within the bilayer membranes of the circulating liposomes. This lipid vehicle serves as an amphotericin reservoir, reducing nonspecific binding to human cell membranes. This helps in limiting the adverse effects without sacrificing the efficacy and also allows for the use of a larger dose of the drug.[12] Amongst the various LFAmBs, L-AMB has the greatest renal protection.[18] Different formulations of AMB have been given by the inhalational route also to avoid nephrotoxicity associated with systemic administration.[9]

Adverse effects: The main adverse effects of conventional AMB include infusion-related events like chills, fever, headache, nausea, vomiting and dose-limiting nephrotoxicity.[19] An increase in intrarenal vascular resistance is the major cause of nephrotoxicity.[14] AMB-associated nephrotoxicity can be reduced by the maintenance of intravascular volume, by avoiding diuretic drugs and saline-loading with 500–1000 ml of normal saline before the infusion of AMB.[20] AMB can also lead to bone marrow depression manifested by anemia.[21] The lipid formulations have several advantages over conventional AMB, such as the increased daily dose of the parent compound (up to 10 fold); high tissue concentration in the lungs, liver and spleen; less infusion related adverse effects (mainly with L-AMB); and marked decrease in nephrotoxicity with L-AMB.[22,23] The three lipid formulations, collectively reduced the risk of the patient's serum creatinine doubling during therapy by 58%.[24] They are now preferred as initial therapy in patients, who are at high risk for nephrotoxicity.[25] They have also proven to be cost-effective as the duration of hospital stay is reduced due to less toxicity.[9]

Indications: The broad antifungal spectrum and experience with the use of AMB accounts for its continued use despite its toxicity problems.[9] It is often used as the initial induction regimen for serious fungal infections and is then replaced by one of the newer azole drugs for chronic therapy or prevention of relapse.[12] AMB is the drug of choice for most forms of invasive candidiasis.[14] LFAmBs are used as second-line or salvage therapy for the treatment of invasive aspergillosis.[26] L-AmB is currently the first-line therapy for disseminated histoplasmosis in HIV-positive or HIV-negative patients, coccidioidomycosis, blastomycosis and sporotrichosis.[9,11] AMB in combination with flucytosine, remains the drug of choice for the treatment of cryptococcal meningitis in patients, whether infected with HIV or not.[11] It is also approved as empiric therapy for the neutropenic patients who have persistent fever despite the use of broad spectrum antibiotics. High doses of L-AMB represents an effective first-line treatment for zygomycosis or mucormycosis.[11] A delay in therapy in patients infected with one of the zygomycetes has resulted in a two fold greater risk for death.[27]

Dose: The recommended dose of IV conventional AMB ranges between 0.7 and 1 mg/kg. Escalating doses of lipid formulations of AMB may be indicated when alternative agents are not available or have been found to be ineffective.[9] The dose range for L-AMB (AmBisome) is 3–5 mg/kg/day; for ABLC (Abelcet) is 5 mg/kg/day and for ABCD (Amphotec) is also 5 mg/kg/day. Intrathecal AMB doses in adults normally range from 0.25 to 0.5 mg diluted in 5 ml of 5% glucose.[28,29]

Azoles

The azole antifungals include two broad classes, imidazoles and triazoles. Both have same antifungal spectrum and mechanism of action.

a. Imidazoles

Imidazoles (clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole and sulconazole) are predominantly used.[14] They have been replaced for systemic administration by triazoles,[30] which include terconazole, itraconazole, fluconazole, voriconazole and posaconazole. Triazoles have more favorable pharmacokinetic profile and improved safety profile than imidazoles. They also have enhanced clinical efficacy in the treatment of systemic mycoses.[31-33]

b. Triazoles

Mechanism of action: They inhibit the Cytochrome P450 enzyme 14 α-sterol demethylase, which prevents the conversion of lanosterol to ergosterol (Fig. 15.1). Inhibition of this enzyme leads to accumulation of toxic methylsterols and results in inhibition of fungal cell growth and replication.[9] The spectrum of action of azoles ranges from many Candida species, cryptococcus neoformans, and the endemic mycoses (blastomycosis, coccidioidomycosis, histoplasmosis), to the dermatophytes, and even the aspergillus infections.[12]

i. *Fluconazole:* It remains one of the most frequently prescribed triazoles because of its excellent bioavailability, tolerability and side effect profile.[9] It is water soluble and well absorbed from the gastrointestinal tract. Its absorption is not affected by food or gastric pH.[34] It has least protein binding and a long half-life of 27–34 hours (in the presence of normal renal function), which can allow once-a-day administration.[16] It has high penetration into CSF ($\geq$ 70% of serum levels) and therefore, used for treating cryptococcal and coccidioidal meningitis.[20] It undergoes 90% of elimination by the renal route.[14]

Adverse effects and drug interactions: Nausea and vomiting may occur at high doses above 200 mg daily. More severe toxicity is unusual. Reversible alopecia, hepatic failure or Stevens-Johnson syndrome have been reported.[14] It has fewer drug-drug interactions than other triazoles. It is an inhibitor of CYP3A4 and CYP2C9. It increases the serum levels of phenytoin, glipizide, glyburide, warfarin, amprenavir and cyclosporine.[14]

Indications: Fluconazole is used in the treatment of candidemia in non-neutropenic patients and is shown to be as effective as AMB in two large randomized trials.[35,36] Fluconazole may be inappropriate for the empirical treatment of suspected fungal infection in neutropenic patients, because prior exposure, as treatment or prophylaxis is associated with resistant candidal strains and also because of its lack of activity against moulds.[37] It is active against most of the *Candida spp.* except C. *Krusei* and *C. glabrata* isolates. If a *C. glabrata* isolate is found susceptible to fluconazole, higher doses (12 mg/kg/d) should be used.[37,38] There is no appreciable activity against; Aspergillus, Fusarium, Pseudallescheria or the Zygomycetes.[9]

It has become the agent of choice for the treatment of coccidioidal meningitis, although relapses have followed therapy with this agent. It is useful for both consolidation and maintenance

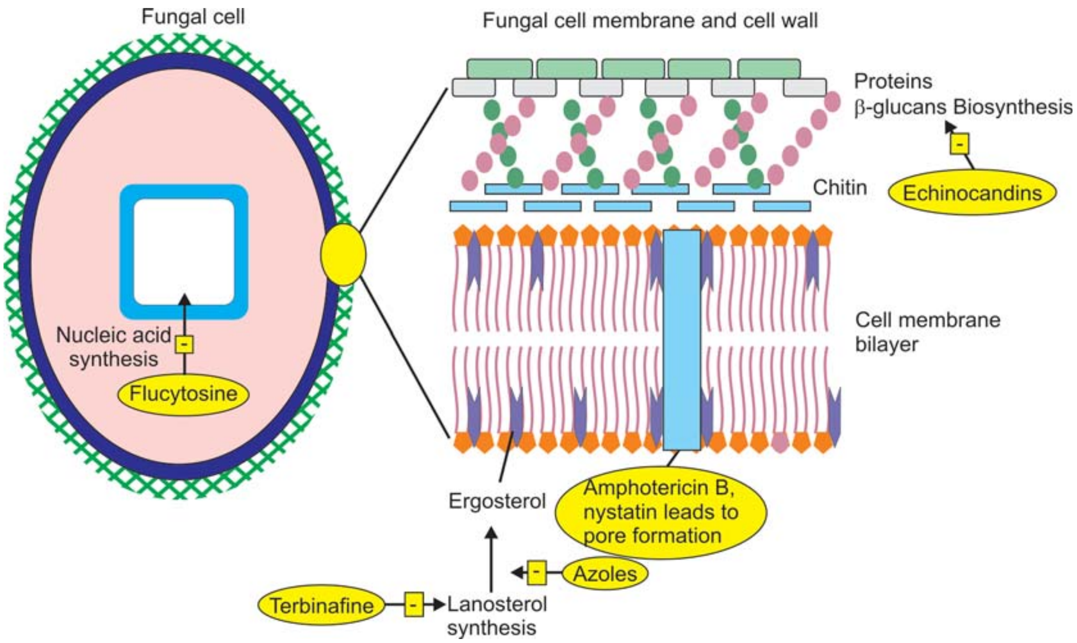

Fig. 15.1: Antifungal agents: Mechanism of action

therapy for cryptococcal meningitis. As, it has greatest penetration into the CSF and vitreous fluid, it is used in the treatment of CNS and intraocular infections.[39,40] Recommended dosage is 50–800 mg once daily, identical for oral and intravenous administration. Children are treated with 3 to 6 mg/kg once daily.[14]

ii. *Itraconazole:* It has a wider spectrum than fluconazole.[7] It is active against yeasts and moulds, with the exception of *Fusarium spp.*, *Scedosporium spp.*, and the Zygomycetes.[41,42] There are few data that examine the use of itraconazole in the treatment of invasive candidiasis.[40] It is generally reserved for patients with mucosal candidiasis, especially those who have experienced treatment failure with fluconazole.[43]

Pharmacokinetics: Maximal absorption of itraconazole capsules depend on the acidic pH. The absorption of the drug is erratic and unpredictable on the concomitant administration of H2-receptor antagonists, proton-pump inhibitors or antacids. It is recommended that itraconazole capsules be taken with food or a cola beverage to increase the absorption.[44] The bioavailability is unpredictable, hence, therapeutic drug monitoring is recommended. Itraconazole is found in equal amounts in plasma as the native drug and as a metabolite, hydroxyitraconazole, which has equivalent antifungal activity to the parent compound. Both molecules are bound more than 99% to plasma proteins. It does not penetrate the CSF.[30]

Indications: This drug has become the standard treatment for lymphocutaneous sporotrichosis, as well as for mild or moderately severe histoplasmosis, blastomycosis and paracoccidioidomycosis and also in certain types of chromoblastomycosis.[20] The development of newer and more effective antifungal agents like voriconazole has relegated itraconazole to second-line therapy during the treatment of Invasive Aspergillosis (IA). Itraconazole is licensed in the United States only for salvage therapy of IA.[26] It is also approved for allergic bronchopulmonary aspergillosis.[26] Oral formulations are dosed in adults at 200 mg 3 times daily for 3 days, then 200 mg once or twice daily thereafter.[40]

Adverse effects and drug interactions: The adverse effects include gastrointestinal symptoms (<10%), headache, dizziness, raised hepatic transaminases (5%), menstrual disorders, peripheral neuropathy and allergic reactions (2%).[45,46] The patients on high doses of itraconazole for prolonged periods are reported to have cardiac failure.[7]

It is metabolized in liver and is a substrate and strong inhibitor of CYP3A4.[30] An important drug interaction is reduced bioavailability of itraconazole when taken with rifamycins.[12]

iii. *Voriconazole:* The spectrum of this drug is similar to that of itraconazole, which also extends to several emerging moulds, including *Fusarium spp.* and *Scedosporium spp.* with the exception of Zygomycetes.[47,48] It also has in vitro activity against many fluconazole resistant *Candida spp.*[49]

Pharmacokinetics: It is formulated as tablets or as a Sulfobutyl-Ether Cyclodextrin (SBECD) solution for IV administration. SBECD and voriconazole dissociate in plasma and follow their own disposition. The cyclodextrin molecule undergoes renal clearance. There are the chances of accumulation of the vehicle in individuals with renal insufficiency.[26] Significant accumulation of SBECD occurs with a creatinine clearance below 50 ml/min. As the toxicity of SBECD at high plasma concentration is unclear, oral voriconazole is preferred in azotemic patients.[14] Bioavailability is 96% after oral administration as either tablet or solution. Oral absorption is reduced by 22% when taken with food, while fatty food reduces bioavailability by 80%.[30,50] The volume of distribution is good (4.6 l/kg), protein binding of the drug is 56%. It is widely distributed in mammalian tissues, with the CSF levels of equivalent to 50% in plasma levels. The elimination half-life is around six hours, which warrants twice-daily dosing.[26]

Indications: It is licensed for the primary treatment of invasive aspergillosis and has been compared with AMB in a non-blinded trial.[51] Significantly, more patients experienced adverse effects with AMB than with voriconazole.[7] Voriconazole is as effective as fluconazole, but less well tolerated in the treatment of esophageal candidiasis.[52] It is also approved for use as salvage therapy in patients with Scedosporium and Fusarium infections.[14] Penicilliosis marneffei also responds well to voriconazole.[53]

Treatment is usually started with IV infusion of 6 mg/kg every 12 hours for 2 doses, followed by 4 mg/kg every 12 hours. It should be administered at 3 mg/kg/hour, not as a bolus. After improvement, the drug is continued as 200 mg every 12 hours. If there is no response, it may be given as 300 mg every 12 hours. It is available as 50 or 200 mg tablets or a suspension of 40 mg/ml when hydrated. Oral drug should be given either one hour before or one hour after meals, as the bioavailability of the drug is reduced by high fat meals.[14] Pediatric patients are known to hyper metabolize voriconazole and for this reason, an IV dose of 7 mg/kg twice daily and oral dosing of 200 mg twice daily without loading is recommended.

Adverse effects and drug interactions: Voriconazole is usually well tolerated. The most common adverse effects include transient visual disturbances with an incidence of 20 to 23%, which are mainly characterized by photopsia, blurred vision and color changes 30 minutes to 1 hour after dosing. Other adverse effects include hepatotoxicity, which may be dose limiting and is manifested by elevated serum bilirubin, alkaline phosphatase and hepatic aminotransferase enzyme levels; skin rash (usually in sunlight exposed areas).[54] QTc prolongation and torsades de pointes should be a consideration in patients with predisposing factors.

Coadministration with rifampin, rifabutin or ritonavir is contraindicated because of accelerated voriconazole metabolism. The dose of voriconazole should be doubled when coadministered with phenytoin, cyclosporine, tacrolimus, rifabutin and warfarin. Coadministration with Sirolimus is contraindicated, as voriconazole increases its area under curve by eleven fold.[14]

iv. Posaconazole: It is an orally-active, extended spectrum triazole.[55] It is insoluble in water and no IV formulation has yet been developed. It is administered as a cherry-flavored suspension using polysorbate 80 as the emulsifying agent. It has a broad spectrum of antifungal activity against moulds like *Aspergillus spp.,* zygomycetes like rhizopus, absidia; dimorphic fungi like blastomyces, coccidioides and *Histoplasma spp.; Fusarium spp.* and dermatophytes like *trichophyton spp.;* and yeasts, e.g. *Candida spp., Cryptococcus spp.* This drug is active against *Candida spp.* isolates that exhibited resistance to other triazoles like fluconazole, itraconazole and voriconazole.

It is available only as a suspension for oral use. Absorption is increased when taken with food, especially with fatty meals. Each dose of posaconazole should be administered with a full meal or with a liquid nutritional supplement in patients who cannot eat a full meal. Moreover, oral absorption is better in divided daily doses and optimal when administered four times daily. It exhibits not only linear kinetics, but also saturable absorption; thus, oral loading doses are not possible. It has large volume of distribution indicating extensive tissue penetration and is highly plasma protein bound (>98%), predominantly to albumin. It undergoes hepatic metabolism and minimal glucuronidation. Renal clearance plays a minor role in its clearance. It is predominantly eliminated unchanged by the fecal-oral route.[9]

Indications: It is approved for the prevention of invasive aspergillosis and candida infections in patients aged $\geq$ 13 years who are at high risk of developing these infections due to the severely immunocompromised state, such as Graft Versus Host Disease (GVHD) in Hematopoietic Stem Cell Transplant (HSCT) patients and also in patients with hematological malignancies with prolonged neutropenia from chemotherapy; it can also be used as salvage therapy for refractory invasive aspergillosis.[56-58]

It is administered as an oral suspension for prophylaxis in the dose of 200 mg three times daily. The duration of therapy is based on recovery from neutropenia or immunosuppression. The dosage for salvage treatment is 800 mg administered in two or four divided doses. Improved efficacy is seen with higher posaconazole levels.[56] It is administered in the dose of 100 mg daily or up to 400 mg twice daily for oropharyngeal candidiasis, which is refractory to fluconazole and itraconazole.[59]

Adverse effects and drug interactions: It is usually a well tolerated drug and the safety profile seems to be more favorable than that of voriconazole. The most frequent adverse effects are headache, gastrointestinal complaints like nausea, diarrhea and vomiting (3 to 12% each in several studies).[56-60] Others include transaminase elevation and hyperbilirubinemia occurring in 3%.[57] QTc prolongation was reported to be as high as 4% in one study.[58] The safety of posaconazole has not been evaluated in children under 13 years old.[30]

v. Newer Triazoles: Despite the incoming of new effective drugs, there are several therapeutic problems, such as new pathogenic fungal species; slow microbiological diagnosis; variable drug bioavailability; toxicity, lack of oral or IV preparations; significant drug interactions for some agents; the development of resistance; and breakthrough infections. Several newer triazoles are in the advanced stages of development to address some of these problems (Table 15.1).

Antimetabolites/Nucleoside Analogues

Flucytosine (5FC; ANCOBON)

Flucytosine has been used to treat candidiasis and other invasive mycoses since 1968.[61] Although not used as

TABLE 15.1: New triazoles on the frontline

Drug	*Route*	*Spectrum*	*Advantages*	*Disadvantages*
Isavuconazole	Oral and intravenous	*Candida spp., Aspergillus spp.,* Dermatophytes	Broad spectrum, water soluble (no need for cyclodextrin), long acting (allows OD up to once-weekly dosing), drug tolerability favorable, limited drug interaction	Most data available as meeting abstracts
Ravuconazole	Oral and intravenous	Similar to isavuconazole and also: *Cryptococcus spp., Chaetomium spp., Trypanosoma cruzi*	Long-acting drug similar to very isavuconazole	Potential for cross-resistance with other azoles
Albaconazole	Oral	*Candida spp., Aspergillus spp., Paecilomyces spp., Cryptococcus spp., Malassezia spp., Trypanosoma cruzi*	Broad spectrum, good pharmacokinetics, excellent oral bioavaialbility	Low concentration achieved in the CSF, Potential for cross-resistance with other azoles

monotherapy, 5FC can be used as an adjunct to AMB or azoles in the treatment of hematogenous candidiasis because of the rapid emergence of resistance when used alone.[62,63] It has clinically useful activity against Cryptococcus neoformans, *Candida spp.,* and the agents of chromoblastomycosis.[14]

It is currently available in only in an oral formulation. More than 90% of the drug is absorbed after an oral dose. The peak plasma concentration is achieved within one to two hours. It is poorly protein bound and has a good penetration into all the body fluid compartments, including CSF.[12] The half-life of the drug is three to six hours in normal individuals. The half-life may be as long as 200 hours in patients having renal failure.[14] The adverse effects are rare if peak levels are kept below 100 µg/ml.[64] Adverse effects like nausea, diarrhea, hepatotoxicity and bone marrow suppression are reversible on discontinuation of the drug.[64] Cytarabine reduces 5FC levels, hence, caution must be employed when used with other myelosuppressive drugs.[7]

The combination of AMB with 5FC has been shown to be effective in randomized controlled trials of patients with cryptococcal meningitis. It is given orally at 100 mg/kg/day, in four divided doses at six hour interval. Dosage should be adjusted for decreased renal function.[14] It is also recommended, in combination, in patients having endophthalmitis, meningitis and endocarditis due to *Candida spp.*[37]

Echinocandins

The newest class of antifungal drugs is the echinocandins. They inhibit β-1, 3-D glucan synthase responsible for the biosynthesis of β-1, 3-D glucan, which is the fungal cell wall biopolymer (Fig. 15.1) These drugs are effective against clinically relevant yeasts and moulds.[65]

Pharmacokinetics: They are synthetically modified lipopeptides. The molecular weight of all three echinocandins is large, which explains their poor oral absorption. All echinocandins have linear kinetics following single-dose IV administration, and have a terminal half-life of 8–13 hours, so once a day usage is appropriate.[66] They are slowly metabolized in the liver by nonenzymatic peptide hydrolysis and/or N-acetylation to inactive low molecular weight products. A lower dose (35 mg/day) is recommended in patients with hepatic insufficiency. Micafungin is metabolized by nonoxidative metabolism within the liver and anidulafungin undergoes nonenzymatic degradation within the kidney. Both these agents undergo fecal excretion. These agents do not require dose adjustment with hepatic impairement.[67] The concentration of these drugs is almost negligible in CSF, vitreous and urine.[68] The efficacy of echinocandins is predicted by peak to Minimum Inhibitory Concentration (MIC) ratios. Optimal fungicidal activity is obtained when peak concentrations exceed MICs by 5 to 10 fold.[67] Echinocandin resistance is uncommon, but may develop during therapy.[68]

A number of in vitro studies have shown a "paradoxical effect" of echinocandins. This refers to the growth of echinocandin-susceptible organisms at highly elevated drug concentrations, far in excess of the MIC (>16 µg/ml) showing break through growth. However, a normal susceptibility pattern is seen with a typical low MIC.[69] The exact mechanism has not been fully elucidated and the clinical significance remains uncertain.[70]

Adverse effects and drug interactions: Caspofungin is generally well-tolerated. The most frequent adverse effects include phlebitis/thrombophlebitis, fever, chills, headache, nausea, vomiting, abdominal pain, diarrhea and rash.[71] Caspofungin is a poor substrate for the Cytochrome P450 enzyme, so a fewer dug interactions occur with it.[65] Daily caspofungin dose should be increased, when administered along with inducers of hepatic metabolism like phenytoin, rifampicin, carbamazepine and dexamethasone. Tacrolimus blood concentration is reduced by 26% when coadministered with caspofungin. Monitoring of tacrolimus blood concentration is essential and the dosage should be adjusted accordingly.

Indications: These drugs have broad spectrum antifungal activity against candida and *Aspergillus spp.* without cross-resistance to existing antifungal agents and are effective against azole-resistant yeasts and moulds.[65,72] They are highly effective on biofilms.[73] They are less active against zygomycetes, cryptococcus neoformans or *Fusarium spp.*[65]

These drugs have excellent safety and tolerability profiles with few drug-related adverse events, which make them attractive options for various fungal infections over other available antifungals.[9] Caspofungin is licensed for the treatment of invasive candidiasis in non-neutropenic adults. It is as effective as AMB in the treatment of candidemia and is also better tolerated.[74] It has its use in the treatment of patients with esophageal candidiasis and is as effective as AMB and fluconazole.[75,76] Caspofungin can be prescribed in patients of invasive aspergillosis, who are refractory to or intolerant to AMB, lipid formulations of AMB and/or itraconazole.[77] For the empirical treatment of presumed fungal infections in patients with febrile neutropenia, caspofungin (50 mg once daily, followed by a loading dose of 70 mg on the first day), is no less effective than liposomal AMB (3 mg/kg once daily).[78]

Micafungin (100 mg IV daily) has been compared to L-AMB 3 mg/kg IV daily in an international, double-blind trial for candidemia and invasive candidiasis. The patients were assigned to IV treatment of 14 days and successful treatment was equivalent in each group. There were less adverse events with micafungin than there were with L-AMB.[79]

Anidulafungin MIC required to inhibit the growth of 90% of organisms (MIC90) value for *C. albicans* clinical isolates is generally lower than 0.5 µg/ml.[80] Also, the isolates of *C. parapsilosis* are susceptible to anidulafungin, but not to caspofungin or micafungin (MIC90 values 2 mg/l, 8 mg/l and 16 mg/l, respectively).[812] Anidulafungin, also, has in vitro activity against *Candida spp.*, growing as biofilms making it a useful addition to the Italian therapeutic armamentarium.[82]

Intravenous dosing regimens for invasive candidiasis with the three compounds are as follows: Caspofungin loading dose of 70 mg and 50 mg daily thereafter, anidulafungin loading dose of 200 mg and 100 mg daily thereafter, and micafungin, 100 mg daily.[40]

Candida and *Aspergillus spp.* (Predominantly *C. albicans* and *A. fumigates*) are two of the most common pathogenic fungi and are associated with significant morbidity and mortality in certain patient groups (e.g. neutropenic patients receiving cancer chemotherapy or patients undergoing stem cell transplantation). Mortality rates of up to 95% are being reported in rapidly progressive IA.[83] However, there has been an increased incidence of less common non-Aspergillus moulds that include zygomycetes, *Fusarium spp.*, and *Scedosporium spp.*[84] Reflecting a key need, important advances have been made in the antifungal armamentarium with the availability of lipid formulations of AMB, triazoles and echinocandins. As the number of patients exposed to echinocandin therapy broadens, the chances for the resistance will also increase.

Miscellaneous Antifungals[86,87]

Nystatin, a polyene antifungal is too toxic for parenteral administration and is mainly used topically for the suppression of local candidal infection. Imidazoles like clotrimazole, miconazole, econazole and others are used for superficial mycoses. Systemic use of ketoconazole has fallen out of clinical use because of its nonselective inhibition of cytochrome P450. Griseofulvin is used only in the systemic treatment of dermatophytoses and has been largely replaced by other antifungals like itraconazole and terbinafine. Terbinafine is a synthetic allylamine, used for the treatment of dermatophytoses especially onychomycosis. Agents like undecyclenic acid, benzoic acid and salicylic acid (Whitfield's Ointment) are very effective in the treatment of tinea pedis.[12,14]

TABLE 15.2: Recommendations for therapeutic drug monitoring of antifungals

Drug	*Indications*	*Timing (days)*	*Goal*
5 FC	Routine during first week of therapy, renal insufficiency, lack of response to therapy	3-5	10-50 µg/ml
Itraconazole	Routine during first week of therapy, lack of response to therapy, gastrointestinal dysfunction, comedication	4-7	Therapy: > 1 µg/ml Prophylaxis: > 0.5 µg/ml
Voriconazole	Lack of response to therapy, gastrointestinal dysfunction, comedication, children; IV to oral switch	4-7	> 0.5-2 µg/ml
Posaconazole	Lack of response to therapy, gastrointestinal dysfunction, comedication	4-7	> 1.5 µg/ml

SPECIFIC ISSUES

Antifungals in Pregnancy

The data on the safety of antifungals for treating patients who are pregnant or lactating are limited. The agents like azoles, griseofulvin and flucytosine should not be used in pregnancy as the risks clearly outweigh the therapeutic benefit. Breast-feeding should be discouraged in women receiving these agents. Successful treatment of systemic mycoses has been documented with AMB in pregnancy with no excess toxicity to either the mother or fetus. Thus, amphotericin B formulations have been the mainstay treatment of antifungal therapy in pregnancy.[85]

Therapeutic Drug Monitoring (TDM)

There is significant interpatient variability for several available antifungal drugs and exposure-effect relationships have been demonstrated for antifungal compounds. TDM is useful to both reduce drug toxicity and optimize efficacy for the following agents. TDM, very well can be incorporated into the patient management (Table 15.2).[86,87]

New Frontiers for Antifungal Therapy

Inhaled L-AMB has been found protective against the development of invasive aspergillosis when given twice weekly to neutropenic patients who have malignancy.[88] Lead compounds that appear promising for antimycotic therapy include nikkomycins, sordarins, lytic peptides, hydroxypyridones and cathelicidins. Other less conventional drug discovery approaches include targeting known traditional virulence factors (e.g. adhesions and secreted enzymes). This approach is based on the principle that killing of the microbe need not occur for an anti-infective agent to be efficacious in the reduction of disease.[85]

Clinical decisions about combination therapy should be based on patient-specific in vivo evaluations. Because of the limited clinical data, combination antifungal therapy should be initiated cautiously. Except for the treatment of cryptococcal meningitis and disseminated aspergillosis, combination therapy should be reserved for the cases of treatment failure (disseminated candidiasis) with no other established pharmacologic options for therapy or for mould infections with high mortality rates.[85]

CLINICAL IMPLICATIONS OF THE ANTIFUNGAL DRUGS

Pharmacotherapy of fungal disease has been revolutionized by the introduction of the newer agents. The following table highlights the Infectious Diseases Society of America (IDSA) guidelines for the management of fungal infections (Table 15.3).

TABLE 15.3: IDSA recommendations for the management of fungal infections

Condition	*Therapy*	
Aspergillosis	*Primary*	*Alternative*
Invasive pulmonary aspergillosis (IPA)	Voriconazole (6 mg/kg IV every 12 hours for 1day, followed by 4 mg/kg IV every 12 hours; oral dosage is 200 mg every 12 hours)	L-AMB (3–5 mg/kg/day IV), ABLC (5 mg/kg/day IV), Caspofungin (70 mg/day 1 IV and 50 mg/day IV thereafter), Posaconazole (200 mg QID initially, then 400 mg BID PO after stabilization of disease)
Invasive sinus aspergillosis	Similar to IPA	Similar to IPA
Tracheobronchial aspergillosis	Similar to IPA	Similar to IPA
Chronic necrotizing pulmonary aspergillosis (subacute IPA)	Similar to IPA	Similar to IPA
Aspergillosis of the CNS	Similar to IPA	Similar to IPA
Chronic cavitary pulmonary aspergillosis	Itraconazole or voriconazole	Similar to IPA
Allergic bronchopulmonary Aspergillosis (ABPA)	Itraconazole	Oral voriconazole (200 mg PO every 12 hours) or posaconazole (400 mg PO BID)
Candidiasis	*Primary*	*Alternative*
Candidemia: Nonneutropenic adults	Fluconazole 800 mg (12 mg/kg) LD[*], then 400 mg (6 mg/kg) daily or an echinocandin[#].	LFAmB 3–5 mg/kg daily; or AmB-d 0.5–1 mg/kg daily; or voriconazole 400 mg (6 mg/kg) bid for 2 doses, then 200 mg (3 mg/kg) bid.
Candidemia:Neutropenic patients	An echinocandin[#] or LFAmB 3–5 mg/kg daily.	Fluconazole 800 mg (12 mg/kg) LD[*], then 400 mg (6 mg/kg) daily; or voriconazole 400 mg (6 mg/kg) bid for 2 doses then 200 mg (3 mg/kg) bid.
Chronic disseminated candidiasis	Fluconazole 400 mg (6 mg/kg) daily for stable patients; LFAmB 3-5 mg/kg daily or AmB-d 0.5-0.7 mg/kg daily for severely ill patients; after patient is stable,change to fluconazole.	An echinocandin[#] for several weeks followed by fluconazole.
CNS candidiasis	LFAmB 3–5 mg/kg with or without 5 FC 25 mg/kg qid for several weeks, followed by fluconazole 400-800 mg (6-12 mg/kg) daily.	Fluconazole 400-800 mg (6-12 mg/kg) daily for patients unable to tolerate LFAmB.
Blastomycosis	*Preferred therapy*	
Moderately severe to severe pulmonary	LFAmB 3-5 mg/kg per day, or AmB-d 0.7–1 mg/kg /day for 1-2 weeks, followed by itraconazole, 200 mg bid for 6-12 months	
Mild to moderate pulmonary	Itraconazole 200 mg once or twice per day for 6-12 months	
Moderately severe to severe disseminated	LFAmB 3-5 mg/kg/day, or AmB-d, 0.7-1 mg/kg/day for 1-2 weeks, followed by itraconazole 200 mg bid for 12 months	
Mild to moderate disseminated	Itraconazole 200 mg once or twice per day for 6-12 months	
CNS disease	LFAmB 5 mg/kg/day for 4-6 weeks is preferred, followed by an oral azole for at least 1 year	

Contd...

Contd...

Histoplasmosis	*Preferred treatment*	
Acute pulmonary histoplasmosis: Moderately severe or severe	LFAmB (3-5 mg/kg daily) or AmB-d (0.7-1.0 mg/kg daily) for 1-2 weeks, followed by Itra (LD* of 200 mg 3 times daily for the first 3 days, then 200 mg twice daily for a total of 12 weeks) Methylprednisolone (0.5-1.0 mg/kg daily IV for 1-2 weeks)	
Mild to moderate	For symptoms of <4 weeks, none For symptoms of >4 weeks, Itra (200 mg once or twice daily for 6-12 weeks)	
Chronic cavitary pulmonary histoplasmosis	Itra (LD* of 200 mg 3 times daily for the first 3 days, then 200 mg once or twice daily for at least 12 months)	
Progressive disseminated histoplasmosis: Moderately severe to severe	LAmB (3 mg/kg daily), LFAmB (5 mg/kg daily), or AmB-d (0.7-1.0 mg/kg daily) for 1-2 weeks, followed by Itra (200 mg twice daily for at least 12 months)	
Mild to moderate	Itra (200 mg twice daily for at least 12 months)	
CNS histoplasmosis	LAmB (5 mg/kg daily for 4–6 weeks), followed by Itra (LD* of 200 mg 3 times daily for the first 3 days, then 200 mg 2–3 times daily for at least 12 months)	
Sporotrichosis	*Preferred treatment*	*Alternative treatment*
Pulmonary	LFAmB 3-5 mg/kg/day, then Itr 200 mg bid; or Itr 200 mg bid	AmB-d 0.7–1 mg/kg/d, then Itr 200 mg bid; surgical removal
Meningitis	LFAmB 5 mg/kg/d, then Itr 200 mg bid	AmB-d 0.7-1 mg/kg/d, then Itr 200 mg bid
Disseminated	Lipid AmB 3-5 mg/kg/d, then Itr 200 mg bid	AmB-d 0.7-1 mg/kg/d, then Itr 200 mg bid

*LD: Loading Dose; #Echinocandins: Doses given in the text

Anti-inflammatory Agents for Asthma

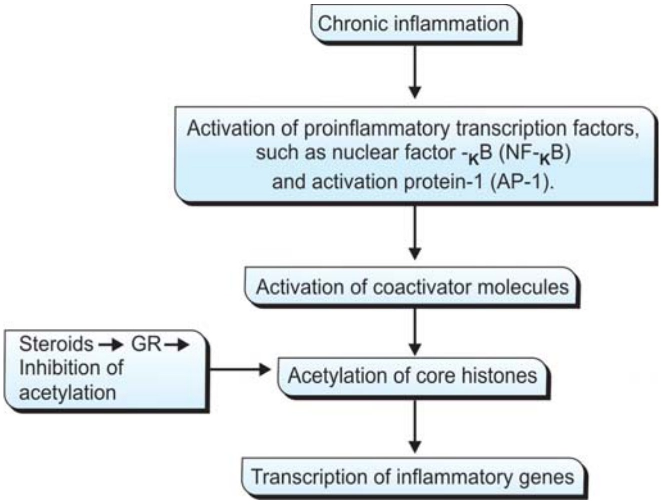
Nusrat Shafiq, Samir Malhotra

INTRODUCTION

The major role of this class of drugs is for long-term control of asthma, these agents are not indicated when rapid bronchodilation is needed. Patients on these drugs must be instructed to keep Short-Acting Beta Agonists (SABAs) with them for quick relief.

CORTICOSTEROIDS

Corticosteroids are amongst the most universal anti-inflammatory agents thereby reducing airway inflammation and hyperresponsiveness. Therefore, they form the cornerstone of asthma management. Both inhalational and systemic routes of administration are used in the management of asthma. Inhalational therapy is highly suitable for maintenance therapy, it needs lower doses and delivers the drug directly to the site of action minimizing the systemic adverse effects associated with corticosteroids. A large number of steroids are available for inhalational therapy, their main differences are in pharmacokinetics, potency (budesonide > beclomethasone > flunisolide), dosing frequency and adverse effects, although most evidence suggests that they do not differ in the terms of efficacy (Table 16.1). Systemic steroids are indicated when inhaled therapy does not work due to severe spasm during acute exacerbations, and also in chronic severe asthma. Dose should not be a deterrent, high dose must be used, usually needed only for five to seven days. Prolonged use of systemic steroids requires to be tapered.



Chronic inflammation
Activation of proinflammatory transcription factors, such as nuclear factor -κB (NF-κB) and activation protein-1 (AP-1).
Activation of coactivator molecules
Steroids → GR → Inhibition of acetylation
Acetylation of core histones
Transcription of inflammatory genes

Fig. 16.1: Transcription of genes during chronic inflammation GR: Glucocorticoid receptor

Mechanism of Action

Their major actions (Fig. 16.1) include, but are not limited to:

- Suppression of inflammatory proteins (Panel 1) caused by the inhibition of genes that encode these proteins. Key among these are inflammatory cytokines (interleukins, TNF-α), chemokines (IL-8, RANTES, MIP-1 α, MCP-1, MCP-3, MCP-4, exotoxins), adhesion molecules (ICAM-1, VCAM-1, E-selectin), enzymes (nitric oxide synthetase and cyclooxygenase and cytoplasmic phospholipase A2), receptors (tachykinin NK-1 and NK-2, bradykinin B2) and peptides (endothelin-1).

- Inhibition of accumulation of mast cells, basophils, eosinophils, dendritic and other cells in the mucosa and submucosa of the lung tissue
- Reduced goblet cell hyperplasia
- Decreased epithelial cell injury
- Decreased vascularity and vascular permeability.

Besides suppressing inflammatory genes, steroids also switch on anti-inflammatory genes like annexin-1 (lipocortin-1), SLPI, interleukin-10 (IL-10) and the inhibitor of NF-κB (IκB-α). Although this effect occurs at high concentrations, it is questionable whether it is seen with therapeutic doses, especially of inhaled steroids. The above-mentioned mechanisms require a lag period of few days before steroid effects can be seen. It has been noted that steroids have other actions that appear earlier, which include: a. their ability to resensitize adrenergic receptors to catecholamines, thereby, potentiating the effects of beta-2 agonists, and b. Contraction of bronchial mucosal blood vessels. The exact mechanisms behind these actions remain unknown.

Pharmacokinetics

Corticosteroids are lipid soluble drugs, therefore, rapidly absorbed from the Gastrointestinal Tract (GIT), as well through inhalation and get widely distributed across the body tissues. They especially the natural steroids, are the highly protein (globulin, albumin and transcortin) bound drugs. Their metabolism occurs mainly in the liver and they are excreted by the kidneys. Natural steroids are metabolized faster than the synthetic steroids, thus, have shorter half-lives, which coupled with their higher affinity for plasma proteins makes them less potent than the synthetic preparations. Many steroids have high first-pass metabolism leading to very low systemic bioavailability, for instance 10% for budesonide, 20% for fluticasone and just 1% for flunisolide.

Systemic steroids are needed for emergency management of asthma, but frequently misused for maintenance therapy. Prednisone is commonly used in asthma (30–60 mg/day) orally in the morning or methylprednisolone 4 mg/kg/day intravenously in four divided doses for severe cases. Hydrocortisone is cheaper than methylprednisolone, but also has mineralocorticoid activity. Once symptoms improve, the doses can be reduced. Some authorities recommend late afternoon administration, if nocturnal asthma is a major problem. A Cochrane review[1] of pooled data from six trials had shown that oral prednisolone (7.5–12 mg/day) was as effective as inhaled steroid (300–2000 mcg/day), but was associated with more adverse effects.

TABLE 16.1: Some commonly used inhaled steroids

Steroids	*Doses*	*Remarks*
Beclomethasone	400 mcg/day in two to four divided doses. Maximum initial dose may go up to 1 mg/day. Pediatric dose is 50–100 mcg/day	Higher doses may be needed if asthma is severe or if usual dose is inadequate
Budesonide	400 mcg/day in two divided doses. Maximum initial dose may go up to 2 mg/day. Pediatric dose is 50–400 mcg/day	Metabolized by CYP3A4
Ciclosenide	160 mcg/day once daily as starting dose, decreased to 80 mcg once daily as maintenance dose	Not used in children
Flunisolide	1 mg/day in to divided doses. Maximum dose 2 mg/day. Maximum pediatric dose 500 mcg twice daily	Dose is lesser (160 mcg twice daily) for CFC free inhaler, maximum dose 320 mcg twice daily. Pediatric dose 80 mcg twice (maximum 160 mcg twice daily).
Fluticasone	200–500 mcg/day in two divided doses. Maximum dose 2 mg/day for severe cases. Pediatric dose 100–200 mcg/day, maximum dose 400 mcg	Most commonly used doses are 0.5–1 mg twice daily
Mometasone	400 mcg inhaled once daily initial dose followed by 200 mcg once or twice daily for maintenance. Maximum dose 800 mcg/day and pediatric dose 110 mcg once daily	The drug should be given in the evening
Triamcinolone	450–600 mcg in three to four divided doses up to a maximum of 1200 mcg/day. Pediatric doses 75 or 150 mcg three to four times up to a maximum of 900 mcg	Also available for oral and parenteral use

DISSOCIATED STEROIDS

There are several problems of steroid therapy in asthma (Table 16.2).

TABLE 16.2: Major drawbacks of steroid therapy for asthma

- Systemic adverse effects even with inhaled drugs
- Local adverse effects and dislike of inhaled steroids
- Poor patient adherence with inhaled steroids seen in 30% to 60% of patients[2]
- Lack of rapid symptom relief
- Complicated treatment regimens[3]
- Inability to properly use inhaler devices, especially in children and elderly

There have been attempts to discover oral novel steroids that lack the adverse effect potential of currently available steroids; such steroids are called dissociated steroids.[4] The concept of dissociated steroids was an attempt to dissociate side effects, which are presumably caused by DNA binding and gene activation (*trans-activation* or *cis repression*) from therapeutic anti-inflammatory effects, which are probably due to the inhibition of inflammatory gene expression by NF-κB and other proinflammatory transcription factors through a non-DNA binding mechanism (*transrepression*).[5,6] It is hoped that this novel class of "dissociated" steroids will have the property for *transrepression* with relatively little *transactivation* and therefore, lesser the incidence of adverse effects.

Adverse Effects of Steroids

Corticosteroids are life-saving drugs with an excellent risk benefit ratio in asthma. However, they have potential to cause a large number of adverse effects, some of which can be severe, and others serious. The adverse effect potential of inhaled steroids is lesser, but may be significant (Table 16.3). It is important to appreciate that while the dose-response curve of inhaled steroids plateaus at higher doses, the dose-systemic absorption curve is linear and continues to rise even at the high doses of inhaled steroids, with the result that even as the therapeutic effects plateau at a dose equivalent to 1600 mcg/day of beclomethasone, the probability of systemic adverse effects continues to rise with rising doses.

Systemic corticosteroid therapy is known to cause a vast number of adverse effects (Table 16.4), their incidence and severity are directly proportional to dose (<7.5 mg/day of prednisolone is usually considered physiological) and duration of treatment, but are not dependent on the type of steroid used. The long history of their use has shown that short-course treatment (<5–10 days) even at high doses does not cause much toxicity. On the other hand, long duration of treatment even at relatively low doses is likely to cause adverse effects. The most common adverse effects during a brief course as is used during asthma exacerbations are mood disturbances, increased appetite, impaired glucose control in diabetics and candidiasis.

TABLE 16.3: Potential adverse effects associated with inhaled steroids[7]

Adverse effect	*Risk*
Hypothalamic-pituitary-adrenal axis suppression	No significant risk until dosages of budesonide or beclomethasone increased to >1500 mcg/day in adults or >400 mcg/day in children
Bone resorption	Modest but significant effects at doses possibly as low as 500 mcg/day
Carbohydrate and lipid metabolism	Minor, clinically insignificant changes occur with dosages of beclomethasone >1000 ug/day
Cataracts	Anecdotal reports, risk unproven
Skin thinning	Dosage-related effect with beclomethasone dipropionate over a range of 400 to 2000 ug/day
Purpura	Dosage-related increase in occurrence with beclomethasone over a range of 400 to 2000 ug/day
Dysphonia	Usually of little consequence. Decreased by mouth rinsing after every inhalation
Candidiasis	Incidence <5%, reduced by use of spacer device and mouth rinsing after every inhalation
Growth retardation	Difficult to separate effect of disease from effect of treatment, but no discernible effects on growth when all studies are considered and normal predicted height is seldom affected

Steroid Withdrawal

There are two main risks of abrupt steroid withdrawal—adrenocortical insufficiency and relapse of disease for which a steroid was being given. It is generally recommended to gradually taper the dose. The UK Committee on Safety of Medicines (CSMs) recommends that moderate dosage with corticosteroids (up to 40 mg daily of prednisolone or equivalent), for up to three weeks, may be stopped without tapering, provided that the original disease is unlikely to relapse, although

TABLE 16.4: Adverse effects associated with systemic steroids

Adverse effects	*Risk and prevention*
Hypothalamic-pituitary-adrenal axis suppression	The most feared complication of steroid therapy, usually occurs with supraphysiological doses used for > 3 weeks and may last for a year or more. The incidence is less when a single morning dose is used, even lesser if used on alternate day.
Bone/joints	Avascular necrosis of bone, may occur with short courses of high-dose treatment (even with inhaled) although relatively uncommon. Osteoporosis is almost universal, if steroids are used for sufficiently long duration, and is greatest in spine, hip, distal radius, pelvis and ribs. Intermittent therapy (alternate day, twice a week) does not appear to reduce the risk. All patients on steroids should be prescribed calcium and vitamin D, advised to exercise regularly, and quit smoking and limit alcohol. There are case reports of rupture of tendons (Achilles and patellar) as well.
Carbohydrate, protein and lipid metabolism	Systemic steroids induce glucose intolerance although diabetic control may be worsened even with inhaled therapy (high doses). Steroids can also cause a catabolic state with protein loss. Besides hyperglycemia, steroids also lead to hypertension, hyperlipidemia, and obesity all of which are established coronary risk factors. Along with this steroids cause body fat redistribution leading to typical Cushingoid features with moon face and buffalo hump.
Immunity	Steroids are potent immunosuppressant drugs, their use can lead to increased susceptibility to infection, aggravation of existing infection, and activation of latent infection. This increased susceptibility to infection coupled with the masking of symptoms can lead to disseminated, often fatal infections (for instance, fungal) with unusual organisms at unusual sites.
Neuropsychiatric	Mood disorders (depression, mania, euphoria), delirium; in children, psychosis, insomnia, and hyperactivity. Memory loss has been reported with parenteral methylprednisolone, which is reversible.
Eye	Cataract, and rarely, retinal detachment.
GIT	It is widely believed that steroids cause peptic ulcers although not all studies have shown increased risk. There also are reports of steroid-induced gastrointestinal perforation with the additional hazard of masking of symptoms due to their anti-inflammatory actions, which can cause delay in the diagnosis.
Skin	Dermatological adverse effects include striae and skin thinning, acne ("steroid acne"), bruising and purpura.
Hypersensitivity	Paradoxically, steroids have been associated with Stevens-Johnson syndrome, hypersensitivity and anaphylaxis
Growth in children	Systemic steroids can impair growth in children and may be used intermittently to reduce this adverse effect.

prophylactic cover may be required for any stress within a week of finishing the course.[8] In practice, there is a large variation in how steroids are tapered from 1 mg monthly to more practical, 2.5 to 5 mg every two to seven days. It must be kept in mind that although gradual withdrawal leads to the normalization of adrenal function, it is not sufficient for conditions associated with stress, such as infection, surgery or trauma, when patients must be given supplementary steroids. It is recommended to withdraw steroids gradually even if patient had received a shorter course of therapy, if (a). higher doses were being given, (b). patient had risk factors for adrenocortical insufficiency, (c). patient had received repeated courses, and (d). patient was taking his or her doses in the evening.

Drug Interactions

Enzyme inducers like barbiturates, carbamazepine, phenytoin, primidone, or rifampicin increase their metabolism, leading to decrease in their effects. An increased risk of hypokalemia occurs with concomitant use of potassium-depleting diuretics, amphotericin B, xanthenes and beta-2 agonists. Concurrent administration with Nonsteroidal Anti-inflammatory Drugs (NSAIDs) leads to increased incidence of GI bleed and peptic ulcers. Reduced efficacy of antidiabetics and antihypertensives may need dose adjustment. There was a case report of severe peripheral edema caused by a synergistic effect of montelukast and prednisone on sodium and water retention in a patient, which did not recur when either drug was used alone.[9]

In asthma, inhaled steroids are the drugs of first choice for prophylaxis and maintenance treatment in patients whose symptoms need regular use of beta-2 agonists. Their regular use decreases bronchial reactivity, provides symptomatic relief, reduces the requirement for inhaled beta-2 agonist "rescue" and also has "systemic steroid sparing effect". Their effects are apparent within a few days to a week, but maximum effects need months of use. Despite these advantages, they cannot be considered as curative drugs; however, there is clinical trial evidence to show that discontinuation of steroids leads to disease exacerbation.

Fixed dose combinations: Fixed dose combinations of steroids with long-acting beta-2 adrenergic agonists are also available, for instance budesonide plus formoterol and fluticasone plus salmeterol. The combination has been shown to be synergistic and provides several advantages; the molecular mechanisms for the same have now been elucidated. It has been shown inhaled beta-2 agonists lead to the increased localization of steroid receptors in the nucleus and provide the additive suppression of release of inflammatory mediators.[10] Steroids in turn increase the expression of beta-2 receptors by increasing gene transcription and prevent their desensitization by restoring coupling of G-proteins with beta-2 receptors.[11,12]

Leukotriene Receptor Antagonists

Leukotrienes, the products of arachidonic acid metabolism have important role in bronchial asthma (Fig. 16.2). They are highly potent bronchoconstrictors, the action is primarily mediated via LT1 receptors.

While montelukast, zafirlukast and pranlukast are cysLT1 receptor antagonists, zileuton is lipoxygenase inhibitor; both the approaches are effective in asthma with decreased frequency of exacerbations (as effective as steroids) and improved asthma control seen in randomized trials. They have been shown to reduce symptoms, increase airway caliber, improve bronchial reactivity and decrease airway inflammation, but to a lesser degree than steroids. The response to therapy is less homogeneous as compared with other anti-asthma drugs and patients can be classified into responders and non-responders; only in responders can these drugs be considered as alternatives to steroids. There are no parameters that can help to predict, which patients will respond. They are taken orally, which leads to a better compliance amongst patients unable to handle inhalers well such as children. However, combination of anti-leukotriene drugs with inhaled corticosteroids may not be as efficacious as a combination of the steroids with Long-acting Beta Agonists (LABAs). Theoretically, zileuton provides several additional advantages over and above LT1 receptor antagonists. Firstly, it inhibits LTB4 synthesis, which is a potent chemotactic autacoid; secondly it inhibits the formation of other 5-lipoxygenase products, which also have a role in the pathogenesis of asthma; and lastly, it inhibit cys-LT effects that are not mediated via LT1 receptors.[13]

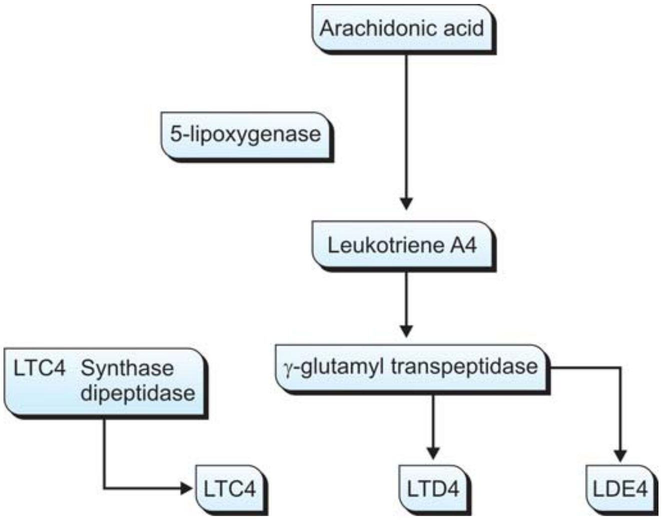


Fig. 16.2: Arachidonic acid metabolism and bronchial asthma

i. *Zafirlukast:* A selective, competitive antagonist of the LTC4, D4 and E4 receptors, this was the first marketed compound of this class. Its peak plasma concentrations occur in three hours; food reduces its bioavailability (by 40%) with reduction in both the rate and the extent of absorption. It is highly (99%) proteins bound, extensively metabolized in liver by CYP2C9, and excreted primarily (90%) by the GIT, the rest in urine, as metabolites. The most common adverse effects seen in 1 to 2% of patients include were headache, rash, abdominal pain, malaise and gastrointestinal disturbances (nausea, diarrhea, dyspepsia). An increased incidence of respiratory tract infection and depression may occur. Less common are fever, malaise, abdominal and joint/muscle pains, insomnia, dizziness, and elevations in liver function tests. Frank hepatitis is rare, but fatalities have been seen. Hypersensitivity reactions (rash, pruritus, urticaria, angioedema), agranulocytosis and bleeding are uncommon.

There are case reports of Churg-Strauss syndrome (systemic eosinophilia) with its use. It is recommended to discontinue treatment, although the causality has remained questionable.[14] In some patients it had occurred after steroid withdrawal, which had led to speculation that asthma might have been a part of some undiagnosed vasculitis, which got unmasked by steroid withdrawal. Others have contended that Churg-Strauss syndrome may have been a precursor of severe asthma. Lastly, similar systemic eosinophilias have been observed in patients taking fluticasone and cromoglycate, a finding that points towards a nondrug cause. On the contrary, Churg-Strauss syndrome has been seen with other leukotriene antagonists, montelukast and pranlukast as well, which points towards a class effect.[15] Therefore, it is now recommended to monitor ESR, CRP and TLC (particularly eosinophils) if the introduction of a leukotriene antagonist allows the physicians to reduce the dose of oral steroids.[16]

Zafirlukast is metabolized by CYP2C9 and inhibits CYP2C9 and CYP3A4. Therefore, use with drugs that are metabolized by these cytochromes may lead to the possibility of increases in plasma concentrations. Patients on warfarin may need dose adjustment as the prolongation of the prothrombin time can occur. Inducers of CYP29 may lead to reduction in plasma concentrations of zafirlukast. Zafirlukast has rarely been reported to increase plasma theophylline concentrations while the concentration of zafirlukast may be increased by aspirin (high dose).

ii. *Montelukast:* Montelukast is probably the most commonly used compound of this class. It reaches peak plasma concentration in three to four hours after oral dose, has an oral bioavailability of > 60%, is more than 99% bound to plasma proteins, metabolized by CYP3A4, CYP2A6 and CYP2C9, and excreted by the GIT. It is similar to zafirlukast in most aspects, but has a longer duration of action. It is also licensed for use in children in reduced doses.

These drugs have been tried with varied success in several other indications, such as in rhinitis, bronchiolitis, cystic fibrosis, eczema, eosinophilic esophagitis, graft-versus-host disease, mastocytosis, sleep-disordered breathing and urticaria. The adverse effect profile is similar to that of zafirlukast. Suspected post-marketing adverse effects reported to the regulatory agencies include edema, agitation and restlessness, allergy (anaphylaxis, angioedema, urticaria), chest pain, tremor, dry mouth, vertigo, arthralgia, depression, suicidality and anxiousness.[17,18]

iii. *Zileuton:* Zileuton is an orally active 5-lipoxygenase inhibitor for use as an alternative adjuvant to long-acting beta agonist and corticosteroids in chronic management of asthma. It is well absorbed from the GIT, the peak levels are seen in two hours. It is highly proteins (93%) bound, metabolized by CYP1A2, CYP2C9 and CYP3A4, and inactive metabolites are eliminated renally. The most common adverse effects are headache, pharyngolaryngeal pain, gastrointestinal disturbances, myalgia and sinusitis. Rarely, hypersensitivity, urticaria, rash, and leukopenia have occurred. Elevated liver enzymes and severe hepatic injury may rarely occur. It is therefore, advisable to monitor liver function once monthly particularly in the first three months of therapy. It may increase the plasma levels (leading to toxicity) of warfarin, propranolol and theophylline.

Leukotriene inhibitors inhibit early and late bronchoconstrictor responses to antigens, not suitable for the acute attacks of asthma. Recently, it has been shown in a randomized trial in adults with acute asthma that intravenous montelukast plus standard treatment produced significant relief of airway obstruction (FEV_1) with an early (10 min) onset of action.[19] These drugs are particularly useful for asthma induced by NSAIDs, cold air and exercise. They can be used along with inhaled steroids in patients with moderate persistent asthma and may have a steroid-sparing. Montelukast has been shown to improve both asthma control and asthma-related quality of life in patients insufficiently controlled with inhaled steroids or inhaled steroids plus LABAs.[20]

MAST CELL STABILIZERS

Two drugs in this category, cromolyn and nedocromil probably act by several mechanisms: Inhibition of the release of mediators from mast cells, inhibition of white blood cell trafficking in airways, reversal of increased leukocyte activation, antagonism of substance P, inhibition of the effects of Platelet-Activating Factor (PAF) and suppression of the effects of chemotactic peptides on blood cells. There is enough clinical evidence to show that pretreatment with these agents blocks allergen-induced bronchoconstriction making them suitable for use before exercise or allergen exposure. Moreover, their long-term use reduces the severity of symptoms and the need for bronchodilators. They are not as effective as inhaled steroids, but combination with steroids improves asthma control. Like anticholinergics, an n-of-1 trial for four weeks can help identify individual patients that respond best (or do not respond) to this class of drugs.

Cromolyn

The first agent in this class, cromolyn is available in inhalational forms, administered in a dose of 2 mg four times daily. The dose may be increased to six or eight times daily, if poor control is a problem. Besides prophylaxis of asthma, cromolyn is also used, with variable success, in prophylaxis and treatment of seasonal and perennial allergic rhinitis, acute and chronic allergic conjunctivitis, vernal keratoconjunctivitis, prevention of food allergies (orally), mastocytosis, Cogan's syndrome, cough associated with ACE inhibitor therapy, nonspecific cough in children, and moderately severe atopic dermatitis (in children).

Poor systemic bioavailability implies fewer incidences of systemic adverse effects. Local adverse effects, such as irritation in the throat, cough, dryness of mouth, bad taste, nasal congestion, tightness of chest, transient bronchospasm and wheezing (aggravation of existing asthma) may occur. Serious adverse effects are uncommon; dermatitis, myositis, joint pain and swelling or gastroenteritis (<2%), dysuria, urinary frequency, rarely pulmonary infiltration with eosinophilia and anaphylaxis, may occur.

Cromolyn is not indicated for the treatment of acute asthmatic attacks. Its withdrawal may lead to recurrence, should therefore be attempted under steroid cover if steroid doses were reduced because of its use. Also, the dose should be gradually tapered over a period of one week.

Nedocromil Sodium

It is similar to cromolyn in most aspects, generally considered to be its alternative except that its duration of action is somewhat longer. It is usually started in dose of 4 mg (inhaled) four times a day. The other uses are similar to cromolyn. It has poor systemic bioavailability from the GIT. The adverse effects are mild, infrequent, mostly transient and do not require the discontinuation of therapy. Paradoxical bronchospasm is rare.

The major indication for the use of mast cell stabilizers is to prevent asthmatic attacks in patients with mild-to-moderate asthma. Nedocromil is not approved for use in patients <12 years of age while cromolyn is approved for use in adults, as well as children.

Anti-IgE Monoclonal Antibodies

Monoclonal antibodies, which bind to the site on IgE antibody to prevent its binding to receptors (FCεR1 and FCεR2) present on mast cells and other inflammatory cells, are a new class of drugs approved for use in certain cases of asthma. Omalizumab is the prototype of this class of "biological drugs".

Omalizumab

It is a recombinant humanized monoclonal antibody targeted against IgE. Once it binds to IgE receptors on inflammatory cells, it prevents interaction of IgE with these inflammatory cells and prevents their release. It is produced in Chinese Hamster Ovary (CHO) cells in cell culture. It is approved for prophylactic use as add-on therapy to standard treatment in adult patients with moderate to severe, persistent, allergic, IgE-induced asthma.[20] It decreases exacerbations, improves quality of life and reduces steroid requirements.[21] It does not have a bronchodilator effect, has no role during acute exacerbations.

The dose is variable, ranging from 75–300 mg every four weeks to 225–375 mg every two weeks. The dose depends on the patient's body weight and pretreatment serum IgE concentrations. It is administered subcutaneously, it is not recommended to give more than 150 mg at one site. Injection site reactions, including erythema, stinging, bruising and induration are the most common adverse effects. Generalized pain, fatigue, arthralgia, dizziness, earache, GI disturbances, headache and alopecia are some other adverse effects. Flu-like syndrome and an increased incidence of infections (parasitic, viral) has been seen. Rarely, Churg-Strauss syndrome, hypersensitivity reactions, including urticaria, dermatitis, pruritus and anaphylaxis are reported. The temporal relation of anaphylactic reactions to omalizumab is unpredictable. The side effects may occur after the first dose or within a few days after a dose, or even more than one year after a patient is on regular therapy. Severe thrombocytopenia and an increased incidence of cancer are two other potentially serious adverse effects with its use.

MISCELLANEOUS DRUGS

Mepolizumab

Mepolizumab, a monoclonal antibody against IL-5 has received an orphan drug status for the management of hypereosinophilic syndrome. When given as an infusion to patients with refractory eosinophilic asthma with a history of recurrent exacerbations, mepolizumab reduced the number of blood and sputum eosinophils, had steroid-sparing effect in patients who had asthma with sputum eosinophilia despite prednisone treatment.[22]

Magnesium Sulfate

Magnesium is known to reduce smooth muscle contraction, decrease histamine release from mast cells, and inhibit acetylcholine release. In a study in pediatric patients with acute severe exacerbation, unresponsive to standard treatment, $MgSO_4$ in a dose of 40 mg/kg IV bolus, led to symptomatic improvement within a few minutes that lasted for about two hours.[23] Similarly, in adult patients with severe, acute asthma, it caused improvement in pulmonary function when used in a dose of 2 g IV, as an adjunct to standard therapy.[24] Nebulized magnesium may also improve symptoms over and above the effects of standard inhaled drugs, the most severely ill derive the most benefit.[25]

Nebulized Lidocaine

The safety and efficacy of nebulized lidocaine was evaluated in a randomized, placebo-controlled trial in 50 patients with mild-to-moderate asthma.[26] Nebulized lignocaine improved the various indicators of asthma severity, such as the FEV_1, night-time awakenings, clinical symptoms, bronchodilator use and blood eosinophil counts.

Inhaled Heparin

In a small study in 12 patients with exercise-induced asthma, nebulized heparin (1000 U/kg) prevented exercise-induced asthma without influencing histamine-induced bronchoconstriction.[27] This non-anticoagulant action of heparin is more likely to relate to the modulation of mediator release than to a direct effect on smooth muscle.

Beta-adrenergic Blockers

Some recent studies have suggested a role of beta-blockers in the management of asthma. This paradox has been likened to the beta-blocker paradox in heart failure. In a preliminary study, the safety and efficacy of escalating doses of the beta-blocker, nadolol (an inverse agonist), administered over 9 weeks to 10 subjects with mild asthma was evaluated.[28] A dose-dependent decrease in airway hyperresponsiveness to methacholine was seen in 8 out of the 10 patients after 9 weeks of nadolol treatment. Clearly, more data are needed before any conclusions can be drawn.

Steroid Sparing Anti-inflammatory Agents

There are various steroid sparing-agents, like azathioprine that have been evaluated. There is a lack of larger, well designed studies to provide evidence for its use. It cannot be recommended for clinical practice as of now.[29] Cyclosporine is another drug that has been evaluated for its steroid-sparing effect. A Cochrane review of 98 patients with severe asthma treated with cyclosporine showed a small, but significant treatment effect for cyclosporine in the terms of steroid dose reduction.[30] It is a drug with a large number of side effects, not recommended for routine use. A Cochrane review of small clinical trials showed a small, but significant treatment effect for gold in the terms of steroid dose reduction.[31] Should not be routinely used because of the adverse effects concern.

Colchicine and dapsone are two other steroid-sparing drugs. There is no reliable evidence to recommend the use of either of them in the management of steroid-dependent asthmatic patients.

Immunosuppressant Drugs

Nusrat Shafiq, Samir Malhotra

INTRODUCTION

Immunosuppressant drugs are mainly used in the treatment of disorders in which autoimmunity has an important role, some malignancies and for prevention of transplantation rejection. There are four main classes of immunosuppressant drugs; glucocorticoids, calcineurin inhibitors, antiproliferative/antimetabolite drugs, and biologics (antibodies). These are briefly discussed below, particularly with reference to their role in pulmonary disorders.

GLUCOCORTICOIDS

Most aspects of glucocorticoids have been discussed in the earlier chapter on anti-asthma drugs. Their role as immunosuppressants is known since the 1960s.[1] The exact mechanism(s) behind their immunosuppressant actions is (are) unknown (Table 17.1). These actions make steroids one of the most effective immunosuppressant and anti-inflammatory drugs. Most of their effects are seen on cell-mediated immunity, they have no or little effect on humoral immunity.

TABLE 17.1: Proposed mechanisms for immunosuppressant anti-inflammatory actions of steroids

- Redistribution of lymphocytes leading to decreased lymphocytes in peripheral blood
- Transcription of various genes involved in immune processes
- Decreased activation of NF-kappa B leading to increased apoptosis of activated cells[2]
- Decreased production of IL-2 by T lymphocytes
- Downregulation of proinflammatory cytokines (IL-1, IL-6)
- Inhibition of proliferation of T lymphocytes cells
- Inhibition of activation of cytotoxic T lymphocytes
- Decreased neutrophils/monocyte-induced chemotaxis
- Decreased lysosomal enzyme release

Alone, or in combination with other immunosuppressant drugs, steroids are used in the treatment of interstitial lung diseases, vasculitides, sarcoidosis, asthma, and other allergic disorders (including drug induced). They are also used in the management of several other autoimmune disorders such as rheumatoid arthritis, other arthritic disorders, Systemic Lupus Erythematosus (SLE), dermatomyositis, psoriasis, other serious dermatological disorders, inflammatory bowel disease, many disorders of the eye, autoimmune disorders of blood, multiple sclerosis, and many other life-threatening disorders. Steroids also constitute the core management of transplant rejection. Prednisone commonly used as an immunosuppressive agent is converted to active prednisolone in the body. It is well absorbed from the Gastrointestinal Tract (GIT), conveniently given once daily in the usual dose of 1 mg/kg/day and tapered once there is clinical improvement. In many disordrers, including in post-transplant cases, it is continued life long. It should be taken with food to minimize GI toxicity. In order to mimic the circadian rhythm, administration between 7 and 8 am is recommended. Methylprednisolone is used in high doses (1 g/day IV) for three days in a month in various immunosuppressive protocols. High doses of methylprednisolone are routinely required for preventing acute graft rejection.

The most important adverse effects of steroids include hypertension, dyslipidemia, hyperglycemia, osteoporosis, avascular necrosis of bone, poor wound healing, increased risk of infections, cataract and growth retardation in children.

CALCINEURIN INHIBITORS

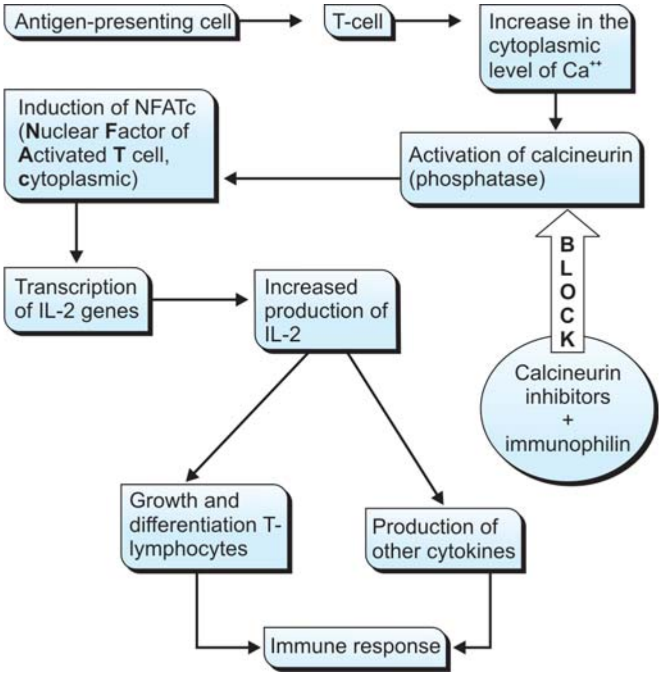
Calcineurin is a protein that activates T lymphocytes. Calcineurin inhibitors (cyclosporine, tacrolimus and pimecrolimus) are among the most efficacious immunosuppressant drugs (Fig. 17.1).

Cyclosporine

Cyclosporine is an 11 amino acid cyclic polypeptide obtained from fungus *Beauveria nivea*. It forms a complex with an immunophilin (cyclophilin) and inhibits T cell responses (Fig. 17.1). When administered orally it is slowly and incompletely (20 to 50%) absorbed. Food has variable effects on its absorption. The various oral preparations, which are available in the market may not be bioequivalent, hence not advisable to switch brands without expert supervision and plasma level monitoring. The absorption also depends on the presence of bile, leading to considerable interpatient and intrapatient variability. The microemulsion formulation of cyclosporine forms a microemulsion spontaneously with aqueous fluids in the GIT, making it less dependent on bile for absorption. The Intravenous (IV) formulation in castor oil needs to be diluted in 5% dextrose or normal saline before injection.

It is extensively metabolized by the hepatic CYP3A, the metabolites are eliminated by the kidneys. Its half-life is 5–18 hours with a considerable inter-individual variation. Because of this variation, toxicity and specialized use in transplant patients, monitoring of blood levels is recommended. The best time to obtain sample is just before the next dose (trough concentration) or at a designated time point after drug administration, two-hour postdose sample has been proposed as a better option.[3]

The daily doses of cyclosporine are different for transplant patients than those with autoimmune disorders. In the treatment of most autoimmune disorders, the usual initiating oral dose is 2.5–5 mg/kg/day in two divided doses, which is reduced once remission is achieved to the lowest effective maintenance dose. In most cases it is not recommended to continue treatment if there is insufficient response within six to eight weeks. The IV doses are one third of oral, given by slow infusion over two to six hours.



Antigen-presenting cell
T-cell
Increase in the cytoplasmic level of Ca⁺⁺
Induction of NFATc (**N**uclear **F**actor of **A**ctivated **T** cell, **c**ytoplasmic)
Activation of calcineurin (phosphatase)
BLOCK
Transcription of IL-2 genes
Increased production of IL-2
Calcineurin inhibitors + immunophilin
Growth and differentiation T-lymphocytes
Production of other cytokines
Immune response

Fig. 17.1: The calcineurin pathway and site of action of calcineurin inhibitors[4]

The pulmonary uses include refractory asthma, sarcoidosis and diffuse parenchymal lung disease. In refractory asthma (in doses of 5 mg/kg/day), it has been shown to improve lung function, decrease frequency of exacerbation, and enable reduction in doses of steroids.[5,6] Adverse effects limit its usefulness.[7] The evidence for its use in sarcoidosis and diffuse parenchymal lung disease is limited. It has also been given by inhalation in the management of acute graft rejection in lung transplantation in doses of 300 mg/day via a nebulizer.[8] One case-control study has shown aerosolised cyclosporine to improve survival among lung transplant recipients with bronchiolitis obliterans.[9] A randomized controlled trial showed that prophylactic use of inhaled cyclosporine did not have a beneficial effect on the rate of acute rejection, but improved chronic rejection-free survival and overall survival.[10]

Renal dysfunction, which may be due to arteriolar constriction, is an important complication of cyclosporine. Hypertension, hyperlipidemia, tremors, hyperuricemia, hirsutism, and gum hyperplasia are the other important adverse effects. It can also lead to GI disturbances, fatigue, hepatotoxicity, headache, hyperkalemia, hypomagnesemia, paresthesias, muscle cramps, anemia, weight gain, infections, edema, thrombocytopenia, rash, pancreatitis, neuropathy, anaphylaxis and anaphylactoid reactions, hyperglycemia, and increased incidence of infections and some tumors (particularly lymphoma, skin cancer and Kaposi's sarcoma).[11]

Because of the risk of anaphylaxis, it is recommended that patients should be "under continuous observation for at least the first 30 minutes following the start of the infusion and at frequent intervals thereafter."[12] In case of anaphylaxis, the infusion should be stopped and epinephrine administered.

It has a large number of pharmacokinetic drug-drug interactions. CYP3A inhibitors (verapamil, nicardipine, fluconazole, ketoconazole, erythromycin, glucocorticoids, HIV protease inhibitors and grapefruit juice) can increase its blood concentration whereas CYP3A inducers (nafcillin, rifampin, carbamazepine, phenobarbital, phenytoin, octreotide, ticlopidine, St John's wort) decrease its blood concentrations.

Because of the large number of adverse effects it also has a number of pharmacodynamic drug interactions. Sirolimus and cyclosporine potentiate each other's adverse effects. Nonsteroidal anti-inflammatory drugs (NSAIDs) and other nephrotoxic agents lead to additive nephrotoxicity. It increases the blood levels of methotrexate, digoxin and statins. There also is the increased risk of myopathy and rhabdomyolysis with statins. Hyperkalemia may occur with the concomitant use of potassium-sparing diuretics and potassium supplements. The risk of gingival hyperplasia may be increased, if used along with amlodipine or nifedipine. It may also reduce the efficacy of live vaccines.

Tacrolimus

Tacrolimus is a macrolide antibiotic produced by *Streptomyces tsukubaensis*. It inhibits T-cell activation by inhibiting calcineurin, but acts on a different immunophilin (FKBP-12) than cyclosporine. Gastrointestinal absorption after oral administration is incomplete (20 to 25%) and variable and food (particularly high fat). It is extensively metabolized by the hepatic CYP3A4 and excreted in feces with a half-life of about 12–16 hours.

Like cyclosporine, it is used for the prophylaxis of solid-organ allograft rejection and for rescue therapy in patients with rejection episodes despite "therapeutic" levels of cyclosporine.[13]

It can be used in autoimmune diseases, but experience with its use is limited. It is currently approved in some countries for the refractory cases of myasthenia gravis, rheumatoid arthritis and lupus nephritis, if steroids are contraindicated. Tacrolimus-releasing stents are commonly used in cardiology to reduce restenosis after coronary artery stent placement.

The adverse effect profile and pharmacokinetic interactions are similar to those of cyclosporine.

ANTIPROLIFERATIVE/ANTIMETABOLIC DRUGS

Sirolimus

Sirolimus is a macrocyclic lactone produced by *Streptomyces hygroscopicus.* After oral administration, sirolimus is rapidly, but incompletely (15%) absorbed.

Sirolimus is indicated for the prevention of organ transplant rejection in combination with a calcineurin inhibitor and glucocorticoids.[14] In patients experiencing or at high risk for calcineurin inhibitor-associated nephrotoxicity, sirolimus has been used with glucocorticoids and mycophenolate mofetil to avoid permanent renal damage.[1] It is also being evaluated in autoimmune diseases. Sirolimus-releasing stents are used to reduce restenosis after coronary artery stent placement and in peripheral arteries to reduce ischemia in severe claudication. It is well known that transplant recipients on immunosuppressant drugs are susceptible to the development of malignancies; there is some evidence to show that sirolimus, coupled with the discontinuation of immunosuppressant drugs, may not only lead to reduced incidence of malignancies, but may also cause tumor regression as seen in the case of Kaposi's sarcoma.[15]

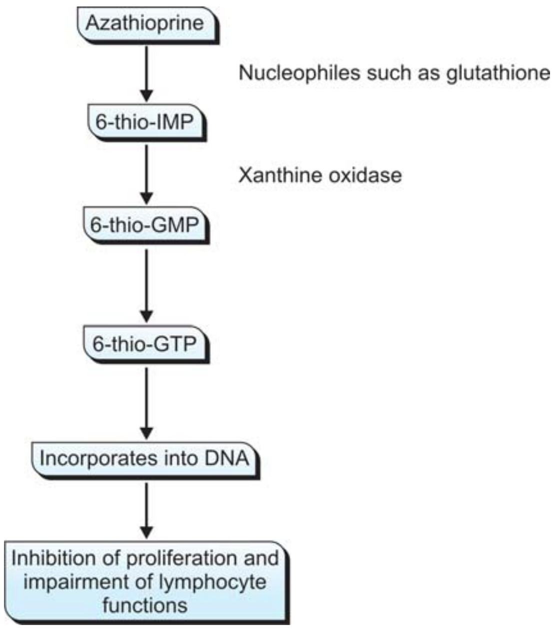
Everolimus

Everolimus is a derivative of sirolimus and resembles it in most aspects. Its indications and adverse effects are similar to sirolimus.

Azathioprine

Azathioprine, a 6-mercaptopurine derivative, is an immunosuppressive antimetabolite drug. It is a purine analog, gets converted to a sham nucleotide 6-thio-IMP and inhibits T-lymphocytes (Fig. 17.2). Azathioprine is well absorbed from the GIT after oral administration. It is rapidly (half-life 10 minutes) metabolized to active mercaptopurine, which is further broken down to many active metabolites having longer half-lives (5 hours).

Azathioprine is used as an adjunct in autoimmune disorders, such as the interstitial lung disorders and for prevention of organ transplant rejection. Its effects may not be seen for several weeks after administration, but if there is no improvement in 12 weeks, it may be discontinued. The starting dose for the prevention of organ rejection is 3–5 mg/kg/day. For autoimmune disorders



Azathioprine
Nucleophiles such as glutathione
6-thio-IMP
Xanthine oxidase
6-thio-GMP
6-thio-GTP
Incorporates into DNA
Inhibition of proliferation and impairment of lymphocyte functions

Fig. 17.2: Mechanism of the action of azathioprine

the recommended dose is 1 mg/kg/day. It is generally used orally, but may also be given by IV infusion over 30–60 minutes after dilution in normal saline or 5% dextrose. Blood counts and liver function tests should be regularly monitored and it should be withdrawn or the dose reduced if blood counts show a downward trend.

The major side effect of azathioprine is dose-related bone marrow suppression, which is generally reversible. It commonly manifestates with leukopenia, thrombocytopenia is less common, anemia is uncommon, and agranulocytosis, pancytopenia or aplastic anemia are rare. Other adverse effects are the GI disturbances, fever, rigors, rash, muscle and joint pains, pneumonitis, pancreatitis, tachycardia, hepatotoxicity (mainly cholestatic), renal dysfunction, hypotension, reversible alopecia, pancreatitis, and increased susceptibility to malignancies and infections (especially varicella and herpes simplex viruses). Rare but potentially fatal adverse effects include the occurrence of veno-occlusive liver disease, Stevens-Johnson syndrome and toxic epidermal necrolysis.

Mycophenolate Mofetil and Mycophenolic Acid

Mycophenolate mofetil is a prodrug rapidly hydrolyzed to active mycophenolic acid. Mycophenolic acid is an immunosuppressant derived from *Penicillium stoloniferum*. It is used along with other immunosuppressants for the prevention of transplant rejection, although its use in combination with azathioprine is not recommended.[16] It is also being investigated in various autoimmune/immune-mediated inflammatory diseases, including arcoidosis, scleroderma, SLE, vasculitic syndromes (Churg-Strauss syndrome, polyarteritis nodosa, microscopic polyangiitis, Takayasu's arteritis, and Wegener's granulomatosis), some others. It is used in doses of 2–3 g/day in two divided doses.

The most important adverse effects are GI (diarrhea, vomiting; hemorrhage and perforation) and hematologic (leukopenia, thrombocytopenia and anemia). There is an increased incidence of infections (particularly CMV sepsis) and malignancies (particularly skin cancer). Aplastic anemia and bone marrow depression may also occur and sometimes fatal.

IMMUNOSUPPRESSIVE CYTOTOXIC DRUGS

Drugs discussed in this category are cytotoxic antimetabolites used mainly as antineoplastic agents, but also possess immunosuppressive effects.

Methotrexate

It is an antimetabolite of folic acid. It acts by competitively inhibiting the enzyme dihydrofolate reductase, which is needed for the formation of tetrahydrofolate. It is rapidly absorbed from the GIT after oral, as well after intramuscular administration. Its half-life is 3–10 hours, but increases (8–15 hours) after high-dose administration. It is excreted primarily by the kidneys.

The main indications are the induction and maintenance of remission in acute lymphoblastic leukemia, non-Hodgkin's lymphomas, and solid neoplasms like choriocarcinoma. Among autoimmune disorders it is used in psoriasis, rheumatoid arthritis, asthma,[17] sarcoidosis,[18] SLE, vasculitic syndromes and others. It has steroid-sparing action in some of these diseases. It is also used to prevent graft-versus-host disease after bone marrow transplantation. The most commonly used dose is 15 mg/m^2 once or twice weekly in malignancies and 7.5–20 mg once weekly in other disorders.

Bone marrow depression (leukopenia, thrombocytopenia and anemia) and GI toxicity (oral ulcers, stomatitis, diarrhea, hemorrhagic enteritis and intestinal perforation) are the common dose-related adverse effects. Hepatotoxicity is the next important adverse effect and cirrhosis can also occur. Folinic acid is given to counter some of the adverse effects of methotrexate, paticularly on bone marrow (folinic acid rescue).

Salicylates, other NSAIDs, probenecid, and some penicillins decrease its renal excretion leading to increased chances of methotrexate toxicity. Co-trimoxazole or trimethoprim coadministration can cause severe methotrexate toxicity. Concomitant use of other drugs having bone marrow, renal or hepatic toxicity may further increase the risk. Folic acid and its derivatives may decrease its efficacy despite the fact that they are used together to reduce methotrexate toxicity.

Cyclophosphamide

It is an antineoplastic drug belonging to the class of alkylating agents and also has immunosuppressant action. It is used in the treatment of non-Hodgkin's lymphomas, many other cancers and autoimmune diseases.

Chlorambucil

It is an antineoplastic drug that belongs to the class of alkylating agents. Its immunosuppressive properties are sometimes utilized in the treatment of autoimmune disorders like sarcoidosis, amyloidosis and Behçet's syndrome. Its major adverse effects include bone marrow suppression, GI symptoms, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis and hepatotoxicity.

MISCELLANEOUS IMMUNOSUPPRESSANTS

Thalidomide

Introduced many decades ago as a hypnotic, it was found to have immunomodulating actions, but its mechanism of action remains unclear. Thalidomide has been used in several autoimmune diseases like graft-versus-host disease, recurrent aphthous stomatitis in severely and terminally immunocompromised patients (HIV-associated wasting syndrome), AIDS-related Kaposi's sarcoma, treatment of the clinical manifestations of both tuberculous and nontuberculous mycobacterial infection, myelodysplastic syndrome, primary brain malignancies, sarcoidosis, Behçet's syndrome, inflammatory bowel disease, SLE, refractory rheumatoid arthritis and several others. Its major adverse effect is its teratogenic potential for which it was withdrawn in the 1960s. The other adverse effects include peripheral neuropathy, venous thromboembolism, constipation, dizziness, orthostatic hypotension and toxic epidermal necrolysis.

Leflunomide

It is an immunosuppressant antiproliferative mainly used as a disease-modifying drug in the treatment of rheumatoid arthritis. It has been tried in other arthritides like psoriatic arthritis and has been investigated in solid tumors, Crohn's disease and ankylosing spondylitis.

In conclusion, the drugs discussed in this chapter have revolutionized the area or organ transplantation and have made significant contribution to treatment of diseases that have autoimmune/autoimmune–-inflammatory components. Most of the times, several drugs are used together. Importantly, these toxic drugs having a large number of serious adverse effects since they inhibit most of the immune responses nonspecifically leading to increased susceptibility to infections and malignanices. Morever, many of these drugs are nephrotoxic, diabetogenic and suppress bone marrow. Nevertheless, it is possible to use them sometimes lifelong, relatively safely, provided proper care is taken with respect to adverse drug reactions.

Biological Agents: Interleukin-2 Receptor Antagonists

Two monoclonal antibodies, basiliximab and daclizumab exert their immunosuppressive effect by binding to the alpha chain (CD25) on the surface of activated T-lymphocytes. This binding prevents the proliferation of T-cells. **Muromonab** is a murine monoclonal antibody to the CD3 receptor on mature human T-cells **(**OKT3). It has been used as an induction therapy in transplant patients. **Alemtuzumab** has been approved for use in B-cell chronic lymphocytic leukemia, its role as an immunosuppressant is increasingly being recognized. Administration of alemtuzumab causes complete lymphocyte depletion. Alemtuzumab, when given as an induction agent along with reduced maintenance doses of immunosuppressants in lung transplant patients led to comparable early survival, rejection and infection rates as compared to conventional high-dose immunosuppression regimens.[19] **Abatacept** has been approved for the treatment of patients with moderate-to-severe rheumatoid arthritis. **Sotrastaurin** is being evaluated primarily in renal transplant patients. Some early studies have also shown efficacy in autoimmune diseases like psoriasis.[20]

Cough in the Adult

Scott E Kopec, Deirdre L Kathman, Richard S Irwin

INTRODUCTION

Coughing is an important reflex that helps protect the lungs from the aspiration of upper airway secretions and from inhaled particles and irritants. It is also an important mechanism for clearing airway secretions. When coughing becomes excessive, it potentially can be the primary symptom for a wide variety of pathological conditions. The symptom of cough is common, and it results in significant costs to the health care system. Cough is a frequent symptom for many life-threatening diseases, and it can negatively impact a patient's lifestyle and the sense of well-being. Therefore, it is vital for health care professionals to understand the etiologies and effective treatments for cough.

The format of this chapter, and its contents, are updates to material that we have previously published on the subject of cough.[1-3]

EPIDEMIOLOGY

Cough is one of the most common symptoms for which patients seek medical attention.[4] From 2001 to 2002, there were over 34 million ambulatory care visits in the US alone for a complaint of cough.[5] This makes up over 3% of all ambulatory care visits. Questionnaires estimate the prevalence of cough to be between 9% and 33% of the population in the US and Europe.[6,7] A survey in rural India reported a prevalence of cough in patients seeking medical attention to be about 3%.[8]

In 2006, over $3.6 billion were spent in the US for over-the-counter cough treatments alone.[9] Because this did not include Wal-Mart pharmacies and Wal-Mart has about 50% of the business, the real cost could be nearly $7.2 billion. If one adds to this the cost of prescription medications to treat cough, the cost of physician visits, and the lost production in the work place due to cough, the overall costs are staggering, with estimates approaching $40 billion annually.[10] In addition, there are other costs to the patient. Patients with cough are viewed by the public as being unhealthy, or having a potentially contagious disease. This in turn may result in a patient feeling isolated, embarrassed, or maligned by the society. The negative impact that chronic cough has on a patient's quality of life is well documented.[11]

PHYSIOLOGY

There are multiple cough receptors in the hypopharynx, larynx, trachea, bronchi, and probably the esophagus, that when triggered, start the cough reflux. These receptors are either chemical receptors or mechanical receptors.[12-14] Cough can be induced by stimulating the chemical receptors with stimuli such as inflammatory mediators and acid. The mechanical receptors can be stimulated by vibration and temperature. Multiple afferent nerves carry the impulse from the sensory receptors to the brainstem, where the cough response is coordinated. The major afferent nerves are c-fibers, which are located throughout the upper and lower airways, and the lungs. In addition to the c-fibers, cough can be triggered by the stimulation of vagal afferent nerves, or a group of receptors called Rapidly Adapting Receptors (RARs). The RAR are mechanoreceptors that respond to physical forces associated with lung inflation and deflation.[15]

The coughing mechanism is divided into three phases. The first phase is the inspiratory phase, which is marked by a deep inspiration. This phase is followed by the compressive phase when the glottis closes, resulting in rising intrathoracic pressure. Finally, the expiratory phase occurs with the sudden opening of the glottis. With an effective cough, expiratory velocities can reach up to 28,000 cm/sec (500 mph).[16] The most important parameter of an effective cough is the linear velocity of the moving air column in the expiratory phase. The linear velocity is determined by the expiratory flow divided by the cross-sectional area of the airways. The higher the flow and the smaller the cross-sectional area, the greater the expiratory velocity. The flow, in turn, is dependent on the initial deep inspiration in the inspiratory phase because expiratory flow rates are greatest at higher lung volumes.

PATHOPHYSIOLOGY

As mentioned above, one of the major functions of cough is to clear excessive secretions for the airway when mucociliary function is not adequate. When the cough is not adequate to serve this purpose, complications, such as gas exchange abnormalities, atelectasis, pneumonia and bronchiectasis, can occur. Clinical disorders that minimize the effectiveness of cough interfere with either the inspiratory or the expiratory phase, or both. What these clinical disorders have in common is an association with the insufficient strength of the respiratory muscles. Some conditions associated with ineffective cough are listed in Table 18.1.[1] It is estimated that a maximal expiratory pressures of less than 40 cm H_2O are associated with an ineffective cough.[17] At the bedside, an ineffective cough can be predicted if the patient is unable, or can barely cough on command.

TABLE 18.1: Conditions associated with an ineffective cough[1]

Pulmonary Disorders
- Asthma
- Bronchiectasis
- Chronic obstructive lung disease
- Cystic fibrosis
- Tracheal lesions (extrinsic compression, intraluminal masses, strictures)
- Tracheobronchomegaly

Extrapulmonary Disorders
- Paralysis/muscle weakness (cervical/upper thoracic spinal cord injuries, Guillain-Barré syndrome, amyotrophic lateral sclerosis, poliomyositis, botulism)
- Pain (rib fractures, postoperative from chest or abdomen surgery)
- Central depression of cough center (drugs, strokes)
- Upper airway obstruction (vocal cord paralysis, laryngeal masses)

BENEFITS OF COUGH

The main benefit of coughing is airway clearance. This benefit is especially important in conditions were the normal mucociliary clearance is overwhelmed such as with a pneumonia. Not only is coughing beneficial in clearing mucus from the airways, it is also important in protecting the lung from retaining inhaled particles and irritants such as the aspiration of upper airway and gastrointestinal secretions. Finally, coughing is beneficial in preventing atelectasis as might occur after intubation, general anesthesia and surgery. Cough has been demonstrated to be highly effective in cardiopulmonary resuscitation, a technique called Cough Cardiopulmonary Resuscitation (CPR). In conscious patients with asystole, profound bradycardia and ventricular tachycardia, coughing can convert the patient back to sinus rhythm.[18] Coughing can help support blood pressure and maintain consciousness in patients in ventricular fibrillation, asystole, or high-degree heart block.[19] Forceful coughing at 1 to 3 second intervals for 30 to 90 seconds is commonly employed in the cardiac catheterization laboratory in patients who develop these arrhythmias as might occur during contrast injection into the coronary arteries. Studies have demonstrated that vigorous coughing can elevate systolic blood pressures to near 140 mm Hg, compared to systolic pressures of about 75 mm Hg generated with well performed chest compressions.[19]

COMPLICATIONS OF COUGH

During the expiratory phase of vigorous coughing, intrathoracic pressures can reach as high as 300 mm Hg.[20] Therefore, it should come as no surprise that these extreme thoracic pressures can result in numerous complications. Table 18.2 lists some of the more common complications of severe coughing.[1,2,21] While coughing can be beneficial in elevating systolic blood pressure, severe coughing can also result in hypotension, most likely due to decreased central venous return that in turn can result in near-syncope or syncope. Patients with cough-induced urinary or fecal incontinence face additional embarrassment that can further worsen their quality of life and self-esteem. In the postoperative patients, severe coughing can place the patient at risk for wound dehiscence. Patients undergoing surgeries, such as hernia repair or cataract surgery should have their coughs controlled before surgery in an effort to avoid intraoperative or postoperative complications.

TABLE 18.2: Complications of severe coughing/ chronic cough*[1,2,21]

Constitutional
- Fatigue/exhaustion
- Excessive sweating
- Anorexia

Neurological
- Syncope/near syncope
- Headache
- Dizziness
- Seizure
- Stroke
- Cerebral air embolism
- Acute cervical radiculopathy

Cardiovascular
- Hypotension
- Nasal and anal vein rupture
- Brady- and tachyarrhythmias

Respiratory
- Exacerbations of asthma/COPD
- Lung herniation
- Pneumothorax
- Pneumomediastinum
- Bronchial rupture

Gastrointestinal/abdominal
- Vomiting
- Gastroesophageal reflux
- Mallory-Weiss tears
- Hernias
- Splenic rupture
- Fecal incontinence

Genitourinary
- Urinary incontinence
- Bladder prolapse
- Vaginal prolapse

Skin/ophthalmological
- Petechiae/purpura
- Disruption of surgical wounds
- Subconjunctival/intraocular hemorrhage

Musculoskeletal
- Rib fractures
- Diaphragmatic rupture
- Costochondritis
- Pulled/torn chest wall muscles

Psychological
- Depression
- Fear of serious disease
- Lifestyle changes
- Decreased self-confidence

*This table includes the most common causes in each category and is not meant to be exhaustive

CAUSES OF COUGH

Many diseases and conditions are associated with cough as a symptom. Cough can be the major symptom for disease processes that are of minor consequences, such as the common cold, or the major symptom of life-threatening conditions, such as a pulmonary embolism. A useful way to categorize the many causes of cough is to divide them up based on the duration of the cough. For example, acute cough is defined as lasting less than three weeks, subacute cough as lasting between 3 and 8 weeks, and chronic cough lasting more than 8 weeks. Table 18.3 lists the more common causes of cough, separated into these three groups.[1,2,21] One should note that several conditions, such as asthma can present as acute, subacute or chronic cough. Of this group, chronic cough contains the widest spectrum of diseases. While acute cough can be due to life-threatening conditions

TABLE 18.3: Differential diagnosis of cough*[1,2,21]

Acute Cough (< 3 weeks)
- Upper respiratory infections (viral, sinusitis)
- Allergic rhinitis
- Pneumonia
- Exacerbations of asthma and COPD
- Congestive heart failure
- Lung cancer
- Pulmonary embolism
- Acute bronchitis
- Acute environmental exposures (dusts, chemicals)

Subacute Cough (3-8 weeks)
- Upper respiratory infections
- *Bordetella pertussis* infections
- Exacerbations of asthma, COPD and bronchiectasis

Chronic Cough (> 8 weeks)
- Upper airway cough syndrome
- Asthma
- Gastroesophageal reflux disease
- ACE inhibitors
- Nonasthmatic eosinophilic bronchitis
- Chronic bronchitis
- Bronchiectasis
- Lung cancer
- Sarcoidosis
- Tuberculosis
- Psychogenic/tic cough/habit cough

*This table includes the most common causes in each category and is not meant to be exhaustive such as infections, lung cancer, congestive heart failure, and pulmonary embolism, the most common causes of acute cough are non-life-threatening conditions, such as the common cold, acute bronchitis, allergic rhinitis and the acute exacerbations of underlying conditions, such as asthma and Chronic Obstructive Pulmonary Disease (COPD).

Acute bronchitis is a condition manifested by cough, with or without phlegm, which lasts for less than three weeks.[22] However, it is a diagnosis of exclusion, as conditions that cause identical symptoms, such as pneumonia, asthma and COPD exacerbations, and the common cold, have to be ruled out. The most common cause of acute bronchitis is most likely respiratory viruses, and the routine use of antibiotics is not recommended.[22] Antitussive agents may provide some short-term symptomatic relief, and inhaled bronchodilators are sometimes used when patients have wheezing in addition to the cough. If a patient with suspected acute bronchitis does not have resolution of their cough after three weeks, an alternative diagnosis should be investigated (see subacute cough below).

The most common cause of a subacute cough is postinfectious cough, especially from infections with *Bordetella pertussis*. Subacute cough from an infection with *B. pertussis* should be considered in patients with cough-induced vomiting, and in patients with the classic whoop (a stridorous sound during inspiration that follows a prolonged episode of coughing). This condition, as well as exacerbations of asthma, bronchiectasis and chronic bronchitis should be considered when patients present with a biphasic course (cough worsens after appearing to improve).

The most common causes of chronic cough in patients with normal chest radiographs are Upper Airway Cough Syndrome (UACS) (previously known as postnasal drip syndrome), asthma, gastroesophageal reflux disease, ACE inhibitor-induced cough, nonasthmatic eosinophilic bronchitis (similar to atopic cough that has been described in Japan), and bronchiectasis. These six disorders account for nearly 95% of all the causes of chronic cough. In addition, patients often have more than one cause contributing to their chronic cough.

Work-up and Management of Acute Cough

A complete history and physical examination are most helpful in determining the cause of acute cough. Postnasal drip and throat clearing with the associated symptoms of nasal congestion, rhinorrhea and sneezing suggest an upper airway cause such as the common cold or allergic rhinitis. Symptoms of chest tightness, wheezing or dyspnea in a patient with a history of asthma or COPD suggest an exacerbation of these diseases as the cause of the acute cough. Some associated symptoms or signs should raise concern to a potentially life-threatening cause of the acute cough. Patients complaining of fever, chest pain, orthopnea or hemoptysis with their cough, or who are found to have crackles, focal rhonchi or an S3 gallop, require further testing, such as a chest radiograph looking for conditions, including pneumonia, congestive heart failure or cancer. We recommend following the diagnostic algorithm published by the American College of Chest Physicians for the work-up of acute cough[3] (Fig. 18.1).

Work-up and Management of Subacute Cough

The most common cause of subacute cough is postinfectious causes. Infections that can leave the patient with a subacute cough include viral upper respiratory infections, such as the common cold, lower respiratory tract infections from respiratory syncytial virus (RSV), and infections with *B. pertussis*. The majority of patients with cough from an uncomplicated common cold will have their cough resolve within three weeks. On the other hand, a high index of suspicion is needed to confirm a diagnosis of *B. pertussis*. While the classic "whoop" may be absent in adults, symptoms of vomiting caused by severe cough episodes suggest a *B. pertussis* infection. During the first two weeks of a *B. pertussis* infection, patients will have upper respiratory tract symptoms suggestive of a common cold, associated with an intermittent nonproductive cough, and sometimes fever. This is known as the catarrhal stage. After approximately two weeks, the patient enters the paroxysmal phase, in which the classic coughing is the hallmark. Protracted episodes of cough-induced vomiting can result in dehydration. This phase typically peaks after two to three weeks, but the cough may persist for two to three months, or longer. The last phase, called the convalescent phase, is marked by less common paroxysmal coughing. During this phase a patient may develop worsening of the paroxysmal coughing if exposed to irritants or another upper respiratory infection.

Common laboratory findings are nonspecific, but may include leukocytosis and an elevated absolute lymphocyte count (> 10,000 cells/µl).[23] Diagnosis of pertussis can be confirmed by the isolation of the organism form nasopharyngeal secretions. However, while this has a 100% specificity, the sensitivity of the culture within the first three weeks of symptoms can be as low as 15 to

Chest. 2006; 129(1Suppl):1-23*

45%.[24] In addition, culture sensitivity decreases with the duration of the infection.[25] Polymerase chain reaction (PCR) for *B. pertussis* appears to have a higher sensitivity, ranging from 65 to 97%.[25,26] As with the cultures, the sensitivity of the PCR decreases with the duration of the infection.[25] Direct fluorescent antibody (DFA) can provide rapid detection of *B. pertussis*, but the sensitivity and specificity are inferior to cultures and PCR. Because no single test has 100% sensitivity, the US Center for Disease Control recommends both cultures and PCR.[27] The CDC has also established guidelines for the method of collecting specimens and the method of testing.[27]

Treatment for *B. pertussis* includes antibiotics, either a microlide or trimethoprim/sulfamethoxazole[28] in the macrolide allergic patient. . While quinolones have *in vitro* activity against *B. pertussis*, studies supporting their use are lacking. Some authors also suggest the addition of oral corticosteroids.[29] If patients are treated within eight days of the onset of symptoms, antibiotics are effective at decreasing the severity of the illness, and decreasing the risk of exposing other patients. Prophylactic antibiotics are also recommended for people exposed to patients with whooping cough.

Some conditions that cause acute cough can also present as a subacute cough if there is a delay in the patient receiving medical attention. COPD and asthma exacerbations, congestive heart failure, lung cancer, and infections such as tuberculosis are examples of conditions that can present as either an acute or subacute cough. We recommend following the diagnostic algorithm published by the American College of Chest Physicians for the work-up of subacute cough[3] (Fig. 18.2).

Work-up and Management of Chronic Cough

When evaluating a patient with chronic cough, it is best to use a systematic approach such as that published by the American College of Chest Physicians[3] (Fig. 18.3). When starting with the history, the character, timing and quality of the cough are often not helpful in determining the etiology. Factors that are important include: Whether or not the patient is an active smoker; if the patient is taking an ACE inhibitor; if the patient lives in the area where tuberculosis or other fungal diseases are endemic; if the patient has a history of cancer, tuberculosis, AIDS; and if the patient has systemic symptoms such as fever, night sweats or weight loss. Other associated symptoms potentially may be helpful. For example, episodic wheezing, dyspnea, and chest tightness might suggest asthma or COPD, but wheezing alone can also be seen in patients with both asthma and UACS. Other

Chest. 2006; 129(1Suppl):1-23*

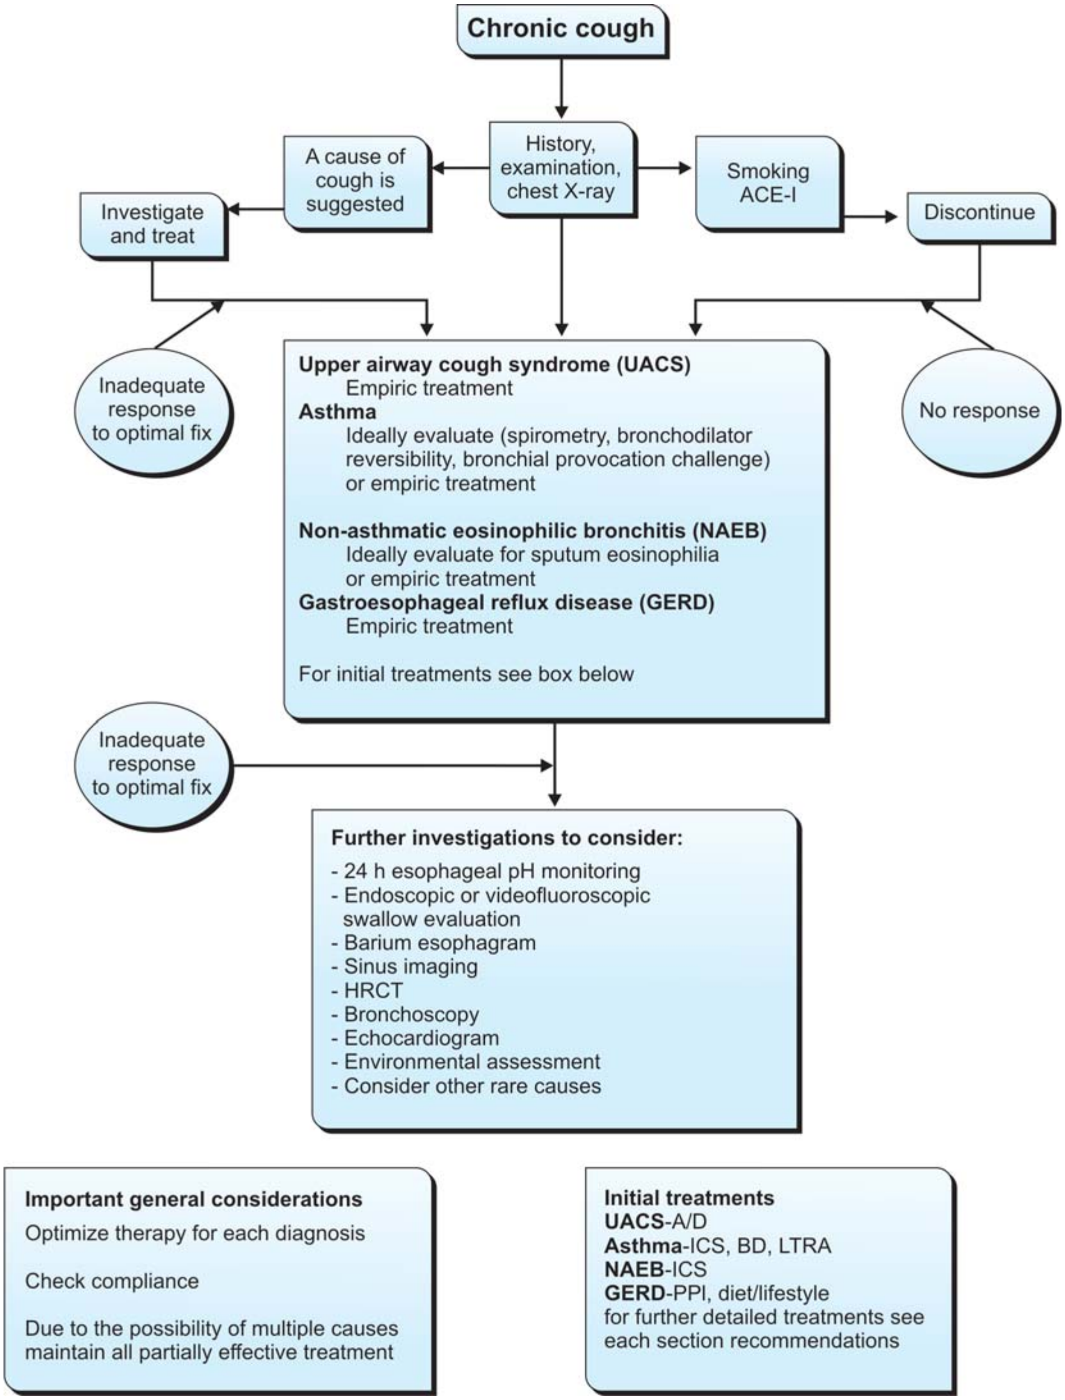
potentially helpful associated symptoms and history will be discussed below with the specific conditions that cause chronic cough. If patients also describe coughing up blood, we suggest following the recommendations in the chapter on hemoptysis.

After a complete history is obtained, a thorough physical examination should be performed. While there are no specific exam findings that are pathognomonic for a specific cause of chronic cough, some findings can help in suggesting a condition contributing to the cough. For example, observing mucopurulent secretions in the oropharynx suggests an UACS due to suppurative upper airway disease, while diffuse wheezing might suggest asthma.

One of the most important tests to order when evaluating a patient with chronic cough is a chest radiograph. When the chest radiograph is abnormal and shows more than inconsequential scarring, the abnormality should be felt to be contributing to the patient's cough until proven otherwise. For example, if the chest radiograph demonstrates findings consistent with congestive heart failure, sarcoidosis or malignancy, further work-up for these conditions followed by the appropriate treatments should be preferentially pursued. One must also keep in mind, however, that an abnormality on chest radiograph may not be associated with the patient's chronic cough (e.g. solitary pulmonary nodule), or the patient may have an additional condition contributing to their cough. In these cases, further investigation, specifically investigating the common causes of chronic cough should be performed, once the conditions suggested by the abnormality have been addressed and the patient continues to complain of cough.

For patients with normal chest radiographs who are not active smokers or taking an ACE inhibitor, the differential diagnosis for chronic cough significantly narrows to one or more of the following: UACS; asthma;



Chronic cough
History, examination, chest X-ray
A cause of cough is suggested
Investigate and treat
Smoking ACE-I
Discontinue
Inadequate response to optimal fix
No response
Upper airway cough syndrome (UACS)
Empiric treatment
Asthma
Ideally evaluate (spirometry, bronchodilator reversibility, bronchial provocation challenge) or empiric treatment
Non-asthmatic eosinophilic bronchitis (NAEB)
Ideally evaluate for sputum eosinophilia or empiric treatment
Gastroesophageal reflux disease (GERD)
Empiric treatment
For initial treatments see box below
Inadequate response to optimal fix
Further investigations to consider:
- 24 h esophageal pH monitoring
- Endoscopic or videofluoroscopic swallow evaluation
- Barium esophagram
- Sinus imaging
- HRCT
- Bronchoscopy
- Echocardiogram
- Environmental assessment
- Consider other rare causes
Important general considerations
Optimize therapy for each diagnosis
Check compliance
Due to the possibility of multiple causes maintain all partially effective treatment
Initial treatments
UACS-A/D
Asthma-ICS, BD, LTRA
NAEB-ICS
GERD-PPI, diet/lifestyle
for further detailed treatments see each section recommendations

Chest. 2006; 129(1Suppl):1-23*

Gastroesophageal Reflux Disease (GERD); chronic bronchitis from environmental irritants such as cigarette smoke or smoke from using biomass fuels; Nonasthmatic Eosinophilic Bronchitis (NAEB); and bronchiectasis. In the US and many other parts of the world, such as southeast Asia, UACS, asthma, and GERD are the cause(s) of chronic cough in over 92% of nonsmokers who are not on an ACE inhibitor and who have a normal chest radiographic appearance.[30] Even in areas where TB is endemic, these three conditions tend to be the most common causes of chronic cough.[31] As mentioned above, these entities may coexist and the cause of chronic cough may be multifactorial. At least 25% of patients with chronic cough have more than one potential cause.[30] It is also important to realize that each of these conditions may present with cough being the only symptom (silent UACS, cough-variant asthma, silent GERD). If work-up for the common causes of chronic cough is unremarkable, one should consider less common causes that account for less than 6% of cases in patients with normal chest radiographs: Bronchogenic carcinoma, chronic interstitial pneumonia, sarcoidosis, and left ventricular failure, among others.[30]

In the initial evaluation of chronic cough in patients with normal chest radiographs, bronchoscopy has a low diagnostic yield. However, if the patient's initial evaluation is negative for UACS, asthma, NAED, and GERD, or the patient fails to respond to optimal treatment for these conditions, a bronchoscopy can yield a positive result up to 28% of the time.[1]

Below is a more detailed discussion on the commonest causes of chronic cough.

Upper Airway Cough Syndrome

In the US, UACS is the most common cause of chronic cough in immunocompetent adults. Patients usually complain of a throat "tickle" or a need to clear the throat, and nasal congestion or discharge. Symptoms may occur after a recent cold and may be accompanied by a wheeze. Approximately 20% of patients with this condition are unaware of the presence of Postnasal Drip (PND) or throat clearing (silent UACS) even though they can be heard to frequently clear their throats in front of loved ones and the physician.[32] The symptoms and physical exam findings reflective of UACS are very sensitive, but not specific, and may include the evidence of nasal discharge, drainage or cobblestoning appearance of the mucosa. The diagnosis of UACS is confirmed if rhinosinus conditions thought to be contributing to postnasal drip are treated and cough is subsequently eliminated.

PND may be a potential stimulus that irritates the afferent limb of the cough reflex in the hypopharynx and/or larynx. In association with hypersensitivity of the cough reflex in the upper airway, it is presumed that direct physical or chemical irritation stimulates the cough reflex peripherally, leading to increased central reactivity.[32] Why some patients with irritated upper airways cough, but many do not is not known. This situation is analogous to the Angiotensin Converting Enzyme Inhibitors (ACEIs)-induced cough situation. While all patients taking ACEIs have excessive amounts of substance P and prostaglandins that are thought to cause hypersensitivity of the cough reflex, it is not known why only some patients develop cough while most do not.

Several conditions cause UACS and include allergic rhinitis, rhinitis medicamentosa, environmental irritant rhinitis, perennial nonallergic rhinitis, postinfectious rhinitis (*Mycoplasma, Chlamydia pneumoniae* and *B. pertussis*), vasomotor rhinitis, allergic fungal sinusitis, bacterial sinusitis, anatomic abnormalities, and rhinitis of pregnancy.[30] Of note, chronic bacterial sinusitis may also be silent, so in patients not improving on decongestants in whom UACS is suspected as the etiology of cough, sinus imaging studies may be helpful. UACS is the principal cause of cough associated with the common cold, making it also the most common cause of acute cough.[32]

As far as treatment is concerned, there is evidence to suggest that older generation antihistamine/decongestant combination medications are more effective than newer generation relatively nonsedating antihistamines, likely secondary to their anticholinergic properties. Intranasal steroids and ipratropium nasal spray, cromolyn, and allergen avoidance are also used. For acute sinusitis, antibiotics directed at the most common organisms are recommended (see the chapter on sinusitis). Intranasal decongestants, such as oxymetazoline may be used in conjunction for symptom relief in the short term. For chronic sinusitis causing cough, a prolonged course of antibiotics (see the chapter on sinusitis) is recommended (at least 2–3 weeks), as well as older generation antihistamine/decongestants and intranasal decongestants twice daily for up to five days, along with intranasal steroids for three months. Allergic fungal sinusitis may require surgical drainage and treatment with oral antifungal agents.

Asthma

In certain patients with asthma, cough may be the primary symptom, or occasionally the only symptom.[30]

This is known as cough-variant asthma. Patients with isolated cough-variant asthma usually have baseline normal spirometry; they have airway hyperresponsiveness and the cough will resolve with asthma treatment.[30] In fact, the diagnosis of asthma as a cause of chronic cough relies upon cough resolution with asthma treatment. A negative methacholine inhalation challenge essentially excludes asthma from the differential of chronic cough. The negative predictive value of a methacholine challenge testing approaches 100% in the symptomatic patient.

Patients with cough-variant asthma respond to the same treatment as patients with the other forms of asthma and should be treated with inhaled bronchodilators, both short- and long-acting as needed, along with steroids, either inhaled, or oral as needed. Leukotriene receptor agonists may also be effective. Inhaled medications should be either a dry powder or a Metered Dose Inhaler (MDI) with a spacer. Because inhaled medications may provoke coughing, this possibility should be assessed and oral medications preferentially prescribed if this occurs. Treatment may take 6–8 weeks before maximum symptomatic benefit is achieved. Of note, if a patient's cough is refractory to inhaled corticosteroids, the presence of airway eosinophilia on induced sputum or bronchoalveolar lavage will identify patients who may benefit from more aggressive therapy.[33]

GERD

The prevalence of GERD as a cause of chronic cough has increased dramatically over the years. Studies accounted for reflux as an etiology of chronic cough in 10% of cases in 1981 and up to 36% of cases in 1998.[34] The term reflux disease is actually the preferred nomenclature over acid reflux disease because nonacid reflux can also contribute and will not respond to acid suppression therapy. Interestingly, in up to 75% of cases, there may be no associated GI symptoms.[34]

While reflux disease may cause cough by aspiration or from irritation of the upper respiratory tract irritation,[34] it most likely causes chronic cough through a vagally-mediated distal esophageal-tracheobronchial reflex mechanism.[35] Furthermore, a cough-reflux perpetuating cycle likely exists whereby cough from any cause may precipitate further reflux.

Risk factors for GERD are many and include certain medications, bisphosphonates, oral corticosteroids, inhaled bronchodilators, and theophylline, progesterone, calcium channel blockers, nitrates, anticholinergic agents, and certain narcotics, such as morphine and meperidine; obesity; smoking; vigorous exercise; alcohol; caffeine; fatty foods, chocolate, citrus juices and tomato products; prolonged intubation; lung transplantation following pneumonectomy; peritoneal dialysis; and variety of respiratory diseases such as asthma and obstructive sleep apnea.[34, 36-38] At this time, esophageal pH and impedance monitoring appears to be the most sensitive and specific test for linking acid and nonacid reflux disease and coughing in a cause and effect manner. An esophageal pH monitoring study by itself is only helpful for evaluating acid reflux, and will not detect episodes of nonacid reflux. A normal esophagoscopy does not rule out reflux disease as a cause of cough, because most patients do not have esophagitis or Barrett's epithelium. For readers interested in reading more about reflux disease in general, we encourage them to read the chapter on this topic and reference.[34]

The 2006 ACCP Cough Guideline Committee recommends empiric therapy for GERD for patients with the following clinical profile: Cough greater than eight weeks, the patient is not exposed to environmental irritants and is a nonsmoker, is not on an ACE inhibitor, and chest radiograph is normal or stable,[34] methacholine challenge is negative, cough fails to respond to a first-generation antihistamine/decongestant medication, and cough has failed to respond to systemic corticosteroids. This profile means that the following conditions have been ruled out: Asthma, UACS and nonasthmatic eosinophilic bronchitis. [34] The mainstay of treatment for reflux disease is acid suppression, prokinetic therapy, and lifestyle and dietary interventions. It is important to let patients know that they may not see improvement for two or three months after initiation of this therapy. Occasionally patients may require antireflux surgery for cases refractory to medical treatment. Failure of medical therapy can be determined by 24 hour esophageal pH/impedance monitoring while the patient continues intensive medical therapy. It is important to keep in mind that GERD may still be the cause if the patient does not respond to treatment because treatment may not be maximal or because medical therapy failed and surgery might be necessary. Up to approximately 85% of patients note improvement in their chronic cough after anti-reflux surgery.[39]

Nonasthmatic Eosinophilic Bronchitis (NAEB)

NAEB is characterized by a chronic cough, normal airway responsiveness to methacholine challenge, eosinophilic airway inflammation in induced sputum samples, and improvement in cough following corticosteroid therapy.[40] While patients usually present with normal baseline spirometry, airflow obstruction can occur if the inflammation is not suppressed. While the cough usually responds to inhaled corticosteroids, systemic corticosteroids may be necessary. The etiology of NAEB is unclear, although it may be associated with exposure to an inhaled allergen or occupational sensitizer. Whenever possible, avoidance from an offending agent is the best treatment.[40] For unclear reasons, NAEB tends to be diagnosed with greater frequency outside the US. Non-US studies have accounted for NAEB as the cause of chronic cough in up to 33% of cases, whereas some US studies have been able to prospectively report successful treatment of chronic cough without reporting a single case of NAEB.[31] It is unclear whether the prevalence is simply greater outside the US or whether it has been traditionally overlooked as a cause of chronic cough in the US. Regardless, it should be considered in all patients with chronic cough. Histologically, this disease is characterized by mast cells within the airway wall, a sign of epithelial infiltration, as opposed to the smooth muscle infiltration by mast cells that is seen in patients with asthma.[40]

Chronic Bronchitis

Chronic bronchitis is defined as a bronchial disease with cough and sputum expectoration occurring on most days for at least three months of the year for at least two years when other pulmonary/cardiac causes of a chronic cough-phlegm syndrome are excluded.[41] It is known to be one of the most frequent causes of cough worldwide.[42] It is caused by the inhalation of irritants: Tobacco, cigar, pipe smoke, passive smoke exposures, hazardous chemicals, organic dusts, cotton, wood, jute, hemp, flax, sisal, grains, manufactured fibers, oil mist, cement, silica, osmium, vanadium, welding fumes, engine exhausts, fumes of cooking fuels[41,43] and fumes from burning biomass. In India, the prevalence of chronic bronchitis among *bidi* and cigarette smokers is 8.2% and 5.9%, respectively.[44] Occupational exposure may account for up to 15% of cases. While most smokers have cough, they are not the group of patients who most commonly seek medical attention for this symptom.

Chronic bronchitis is associated with airway inflammation, mucus hypersecretion, and impaired mucociliary clearance. Additionally, the airways of patients with chronic bronchitis are thought to have heightened responsiveness, albeit, not in the range seen in asthmatics. Progressive airflow obstruction can lead to an ineffective cough due to decreased expiratory flow and impaired mucociliary clearance that can cause the retention of secretions, further aggravating the cough reflex; thereby promoting a cycle of recurrent cough.[41]

There are increased numbers of neutrophils and macrophages seen on bronchoalveolar lavage of patients with chronic bronchitis. The inflammation causes structural changes: Mucus gland hyperplasia, bronchiolar edema, smooth muscle hypertrophy, and peribronchiolar fibrosis that leads to the narrowing of the small airways.[45]

Treatment should focus on reducing sputum production and the reduction of airway inflammation by removing irritants (e.g. tobacco cessation). In patients without severe airflow limitation, cough has been shown to disappear or markedly decrease in 94 to100% of cases with smoking cessation, often within four weeks.[19] Mucolytics often do not help. Ipratropium has been shown to decrease sputum production. While anticholinergics and/or inhaled corticosteroids and long-acting bronchodilators have been shown to decrease exacerbations, antibiotics and systemic corticosteroids serve to decrease cough during severe COPD exacerbations.

Bronchiectasis

In prospective studies, bronchiectasis has caused chronic productive cough with sputum production in approximately 4% of cases.[46] Recurrent bacterial colonization and infection or bronchial obstruction causes airway injury, mediated by neutrophils, lymphocytes, and inflammatory mediators that result in the destruction of the elastic and muscular components of bronchial walls. The result is the dilation of involved airways. Some disorders predisposing patients to bronchiectasis include bronchial obstruction, pneumonia, cystic fibrosis, primary ciliary dyskinesia, allergic bronchopulmonary mycoses, rheumatoid arthritis, inflammatory bowel disease, hypogammaglobulinemia, alpha-1 antitrypsin deficiency, HIV infection, and Marfan's syndrome, among others.[46] Diagnosis is based on history, chest radiography, high-resolution chest CT scans, and the response to targeted therapy. The cough associated with bronchiectatic flares is treated with chest physiotherapy, systemic antibiotics, and drugs to stimulate mucociliary clearance.[46] There has been no proven benefit of oral steroids or long-term prophylactic antibiotics to treat chronic cough associated with bronchiectasis.

Nonbronchiectatic bacterial suppurative airway disease has also been described as a cause of chronic cough.[47] These patients will have excessive purulent secretions in their central airways and positive bacterial cultures, yet have little to no productive cough, and no radiographic evidence of pneumonia or bronchiectasis. Diagnosis is made by bronchoscopy, and patients often respond to prolonged IV antibiotics (3 weeks) after courses of oral antibiotic have been shown to be ineffective.[47]

Postinfectious Cough

The condition refers to cough that comes on following a respiratory infection and disappears with or without treatment within four weeks. It can present with transient bronchial hyperresponsiveness, and/or prolonged upper and lower airway inflammation that resolves as diagnostic and therapeutic studies are pursued.[31] It may be a consequence of *B. pertussis* infection, or may be involved in perpetuating chronic cough by precipitating GERD.

Bronchogenic Carcinoma

Bronchogenic carcinoma is most commonly due to smoking; cough is present in 65% of patients at the time of lung cancer diagnosis.[48] Chest radiography results have a positive predictive value for bronchogenic carcinoma of 36 to 38%, and markedly diminish the likelihood of lung cancer when chest radiographs are normal.[30, 49] Along with chest radiographs, chest CT scans, sputum cytology, flexible bronchoscopy are all used for diagnosis, particularly in patients for whom you have a high index of suspicion of cancer (e.g. cigarette smoker). Surgery to remove Non-Small Cell Lung Cancer (NSCLC) in patients with stage I and II disease is the treatment of choice. For patients with more advanced disease, external beam radiation and/or chemotherapy are the treatments of choice.

Newer chemotherapeutic agents like gemcytabine, can palliate the cough.[48] Localized endobronchial treatment options (e.g. brachytherapy) exist for patients with advanced disease and symptoms of dyspnea and hemoptysis. This may palliate concomitant cough; however, this type of treatment would not be an option for patients with cough alone. Some patients require narcotic antitussive agents to control cough associated with lung cancer.

ACEI-Induced Cough

The cough associated with ACE inhibitor use is typically nonproductive and described as an irritating/tickling/scratching sensation in the back of the throat. Cough has been found to be a class effect and not dose related; therefore, in patients who complain of cough who are on ACE inhibitors, switching to a different class of antihypertensives is recommended. Because angiotensin-receptor blockers are not associated with an increased incidence of cough and they have been shown to have many of the same benefits as ACE inhibitors, they are an excellent substitution choice. The incidence of cough due to ACEIs in the series of patients with chronic cough is 0 to 3% of cases and may appear within a few hours to weeks or months after initiating therapy with an ACE inhibitor.[30] Some symptomatic relief may be obtained by adding sulindac, indomethacin, nifedipine, picotamide, and inhaled sodium cromoglycate when patients are unable to come off of their ACE inhibitors; however, discontinuation of the offending medication is the preferred treatment.[50] Cough secondary to an ACE inhibitor should disappear or markedly improve within the four weeks of discontinuing the medication; however, on occasions, cough may take up to 3 months to completely resolve.[51]

Habit Cough/Tic Cough/Psychogenic Cough

The diagnosis of habit/psychogenic cough is a diagnosis of exclusion. More common causes of cough and less common causes, including tic disorders should be ruled out before labeling a patient with this diagnosis. A key to making a final diagnosis of habit or psychogenic cough requires that cough improve with behavior modification or psychotropic therapy. If a patient's cough persists despite thorough evaluation and psychiatry evaluation and behavior modification, it should be labeled unexplained cough, rather than psychogenic or habit cough.[52]

Miscellaneous Causes

A variety of unusual causes of cough are listed in Table 18.4. [53] Because the more common causes of cough can be the cause of chronic cough 50% of the time in patients with chronic interstitial lung diseases, chronic interstitial pulmonary disease should not be assumed to be the cause of the cough until the more common causes have been adequately evaluated and treated.

Endobronchial abnormalities (tumors, TB, sarcoidosis, retained sutures) occasionally cause chronic cough.[53] Bronchiolitis (nonbronchiectatic suppurative airway disease) affects the small airways and is caused by infections, toxins, systemic diseases, such as inflammatory bowel disease, drug reactions, and transplant recipients, and is another less common cause of chronic cough.[54] Because these etiologies are uncommon causes

TABLE 18.4: Uncommon causes of chronic cough*[53]

Pulmonary (airway)
- Tracheomalacia/Bronchomalacia
- Foreign bodies/Airway stents
- Tracheobronchomegaly
- Tracheobronchopathia osteochondroplastica
- Broncholithiasis

Pulmonary (interstitial)
- Lymphangioleiomyomatosis
- Langerhans cell histiocytosis
- Pulmonary alveolar proteinosis
- Pulmonary alveolar microlithiasis

Connective tissue diseases
- Relapsing polychondritis
- Scleroderma
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Sjögren's syndrome
- Giant cell arteritis
- Wegener's granulomatosis

Gastrointestinal disorders
- Tracheoesophageal fistula
- Inflammatory bowel disease

*This listing is not meant to be exhaustive

of cough, one needs a strong index of suspicion based on the patient's clinical and laboratory picture.

Chronic Cough in the Pediatric Population

Unlike the adult population, a chronic cough in children less than 15 years old is defined as a cough lasting more than four weeks. A comprehensive approach for evaluating a patient < 15 years old with a chronic cough is presented in the ACCP Evidence-based Clinical Practice Guideline.[55] For patients 15 years of age and older with a chronic cough, one should follow the above mentioned guidelines for adults (Fig. 18.3).

Cough in the Immunocompromised Patient

Cough is a very common symptom in patients with compromised immune systems. The initial evaluation for immunocompromised patients presenting with an acute cough depends on the degree of their immunosuppression. HIV-positive patients with CD4 counts > 250 μl who present with acute cough are most likely to have upper respiratory infections, acute bronchitis and acute sinusitis, with less than 5% having bacterial pneumonia or *Pneumocystis* Pneumonia (PCP).[56] For patients with CD4 counts below 250 μl, upper respiratory infections and acute bronchitis still account for almost 45% of the causes, but the number presenting with pneumonia increases to over 23%, including PCP, bacterial pneumonia and TB.[56]

When considering the etiology of chronic cough in patients who are immunocompromised, it is also important to access the nature and severity of their immune defect. For instance, patients with HIV who have CD4 counts of greater than 200 cells/μl are less likely to have chronic cough secondary to *Pneumocystis* pneumonia or from other opportunistic infections. The etiology of chronic cough in these patients is the same as what would be expected in the immunocompetent patients.[57] However, in patients with severely weakened immune systems, especially when their chronic cough is associated with systemic symptoms, such as fever, weight loss or thrush, infections from *Mycobacterium tuberculosis* and opportunistic infections, such as *Pneumocystis* need to be considered.[58] A general rule to remember is as follows: If CD4 less than 200 μl, evaluate the patient for opportunistic infections. If the CD4 count is greater than 400 μl, evaluate the patient as if they had a normal immune system. For CD4 counts between 200–400 μl, the patient's clinical condition matters. If the patient is cachectic, has evidence of oral thrush, or known prior infections with opportunistic organisms, evaluate the patient for opportunistic infections. If the patient is otherwise healthy appearing, initially evaluate them as if they have a normal immune system. Although tuberculosis has been reported in all countries, it remains a highly prevalent disease in developing countries. In fact, it is estimated that approximately 1/3rd of the world's population is infected with *Mycobacterium tuberculosis*, that approximately 9 million people develop active TB each year, and approximately 1.9 million people die from tuberculosis each year.[59] Cough is a cardinal symptom of tuberculosis, and contributes to its transmission. Despite the higher prevalence of tuberculosis in the developing world, it is still not a common cause of chronic cough.[60] However, because it is highly contagious and causes significant morbidity and mortality for those infected, it should be considered in all patients with chronic cough who are at risk for tuberculosis, and patients who are immunocompromised, especially with HIV. For patients who are at high risk for tuberculosis, the World Health Organization recommends that their cough be considered "chronic" after two to three weeks and evaluation begun to rule out infections such as tuberculosis.[61] Sputum for AFB smears and culture, and chest radiograph when possible is recommended for initial evaluation for tuberculosis.

Patients who are immunosuppressed for reasons other than HIV are also at the risk of having infections, such as tuberculosis and *Pneumocystis* pneumonia as the cause of their chronic cough. Such patients include those with neutropenia; chronic disease, such as diabetes, cancer and renal failure; and patients receiving chronic corticosteroids.

Cough due to Parasitic Infections

Special attention is needed when evaluating a patient with chronic cough who resides in an area were certain fungal or parasitic diseases are endemic.[59] While this is especially true when evaluating an immunocompromised patient with chronic cough, immunocompetent patients are also at risk for these infections. For example, paragonimiasis needs to be considered as a potential cause of chronic cough in patients who live or travel in the southeast Asia, especially in Japan, Korea, the Philippines, Taiwan, and parts of China.[62] These patients should be evaluated for the presence of eosinophilia and elevated IgE levels. The chest radiograph can have various appearances, such as pulmonary nodules, cavitary lesions, lymphadenopathy, pleural effusion or pneumothorax. The diagnosis can be confirmed by identifying *Paragonimus westermani* eggs in stool, sputum, pleural fluid or in bronchoalveolar lavage.

Syngamosis is another rare cause of chronic cough. It is the result of infestation by the nematode *Syngamus laryngeus* in which the parasite lodges itself in the tracheobronchial tree of a human after the ingestion of contaminated food or water. It remains unclear if the parasite migrates from the larynx, or is spread hematogenously after absorption from the GI tract. Symptoms include cough, fever, malaise, leukocytosis and eosinophilia. While uncommon in humans, it tends to occur geographically in the Caribbean islands and Brazil.[63] Diagnosis is established by the visualization of copulating reddish-brown worms in the upper airway on bronchoscopy or in expectorated sputum.[64] Cough and other respiratory symptoms reportedly subside after the removal of parasites from the bronchial tree.

Other parasitic infections associated with a chronic chough include ascariasis,[65] leishmaniasis,[66] malaria,[67] and schistosomiasis.[68]

Treatment

Following utilization of a systematic diagnostic protocol, specific therapy has been reported to have a success rate of 84 to 98%. Therefore, because of the high probability of being able to determine the specific cause of cough and prescribe specific therapy that can be successful, there is a limited role for nonspecific therapy that has been comprehensively reviewed elsewhere.[69]

CONCLUSION

Cough is one of the most common symptoms for which patients seek medical attention. While cough is a normal defense mechanism to clear secretions and foreign material from the airways, it can also result in clinically important complications. Cough is also a common symptom for a wide spectrum of both life-threatening and non-life-threatening illnesses. Dividing cough into acute, subacute and chronic categories, based on its duration, is most helpful in constructing the lists of differential diagnoses. Once the cough is categorized into one of these groups, a systematic approach to evaluating and treating the patient has the best chance of being successful in eliminating cough.

Hemoptysis

Andrés F Sosa, J Mark Madison, Paulo J Oliveira

INTRODUCTION

The term hemoptysis refers to the coughing of blood that emanates from the lungs or airways below the larynx.[1] It is an alarming sign for most patients and physicians, the basis of which is the fear that it represents a serious ailment.[2] In 1953, hemoptysis implied tuberculosis for the average medical student[3] and it continues to be so in the developing world;[4] however, bronchiectasis, bronchitis and bronchogenic carcinoma are now the most common causes in the developed world.[5]

Hemoptysis is the primary complaint in 8 to 15% of patients presenting to the chest clinics.[6,7] It may range from scant streaking of sputum, as often seen in chronic bronchitis, to more severe life-threatening quantities of blood that have the potential to cause significant gas exchange abnormalities.[8] It is useful to categorize the amount of hemoptysis according to the rate of bleeding. Hemoptysis is mild when there are less than 20 ml in 24 hours, moderate or submassive when 20-600 ml and massive when more than 600 ml in a 24 hour period. Gross or frank hemoptysis may be defined as the expectoration of a lesser amount than massive hemoptysis and yet more than mere blood streaking. The faster the bleeding, the greater the risk of mortality, which reaches 37% when bleeding exceeds 600 ml in 48 hours and 52% when more than 600 ml in less than 16 hours.[9-11] The rate of blood loss above 15 ml per hour substantially increase the risk of death due to asphyxiation or exsanguination.[12] These volumetric, quantitative definitions are often quoted in texts, but in practice quantification of the amount of coughed out blood is difficult. What may be more relevant and useful is a qualitative definition based on the magnitude of clinical consequences incurred by the patient with hemoptysis. The vast majority of patients with massive hemoptysis die due to asphyxiation, not exsanguination.[12] The anatomical dead space of the major airways is approximately 100-200 ml. Thus, a brisk bleed of 150 ml, for example, could lead to major airway obstruction and the rapid demise of the patient due to inability to oxygenate and ventilate.

It is important not to confuse hemoptysis with bleeding that originates from sources other than the lower respiratory tract, also referred to as "pseudohemoptysis". Patients may not be able to describe the source of their bleeding and, blood arising from the nares, oral cavity, tongue and pharynx penetrate into the larynx to stimulate the cough reflex.[7,13-15] Hematemesis, as well, may be aspirated into the respiratory tract to cause pseudohemoptysis.[15] Also, in hospitalized patients who have received broad-spectrum antibiotics and mechanical ventilation, colonization of the oropharynx by *Serratia marcescens* may produce a red pigment, prodigiosin, that can be mistaken for blood.[16] It should be kept in mind, however, that infection with *Serratia marcescens* can lead to necrotizing pneumonia, presenting with true hemoptysis. Overdose with rifamycin antibiotics can imbue tracheobronchial secretions with a reddish hue that can be mistaken for blood-tinged sputum.[17] Finally, there is also the possibility of factitious hemoptysis. In these cases, the episodes of hemoptysis are self inflicted, this may lead to an unnecessary and extensive diagnostic work-up.[18]

ANATOMY

The lungs have a dual vascular supply. The pulmonary vasculature is a low-pressure system that supplies the lung parenchyma to support gas exchange and the respiratory bronchioles. The bronchial arteries, part of the systemic vasculature, are a high-pressure system that supplies the airways, from the trachea and mainstem bronchi to terminal bronchioles, the peribronchial and perivascular connective tissue, the middle third of the esophagus, the visceral diaphragmatic and mediastinal pleura, intrapulmonary lymphoid tissue, pulmonary vessels and nerves. Bronchial arteries generally originate from the aorta or intercostal arteries. There are usually 2 to 4 bronchial arteries in total and they tend to be more numerous on the left side.[19,20] Arterial and venous communications between both vascular systems occur at the level of the terminal and respiratory bronchioles and the two systems complement each other by maintaining constant flow. The bronchial circulation is the source of over 90% of cases of hemoptysis.[21]

ETIOLOGY AND PATHOGENESIS

The source of hemoptysis depends on the location of disease. If the disease process is located within the lung parenchyma it will involve the pulmonary circulation, but if it is contained within the airways it will involve the bronchial circulation. Chronic disease processes involving the airways and parenchyma will frequently lead to increased vascularity (neovascularization, engorgement and the enlargement of the local blood supply, increased anastomoses with the pulmonary circulation) and friability/fragility in the compromised areas.[22] There are over 140 causes of hemoptysis, which have been described. For practical purposes the causes can be divided into several major categories (Table 19.1).[8,18,23-131]

Nonmassive hemoptysis accounts for the majority of cases (bronchitis being one of the most common cause), but there is a considerable overlap between the massive and nonmassive causes of hemoptysis. The most common causes of massive hemoptysis, accounting for more than 60% of cases,[132-134] are active tuberculosis, bronchiectasis, mycetoma and bronchogenic carcinoma (Table 19.2). As mentioned previously, categorizing the severity of the hemoptysis has significant implications for prognosis and further management.

Infection and Inflammation

Patients with chronic bronchitis have increased vascularity beneath the endobronchial surface. The mucosa is friable and prone to bleed, especially in the presence of bacterial or viral infections.[135] Chronic bronchitis is a major cause of hemoptysis in the United States.[136] Bronchiectatic airways are also prone to bleeding episodes due to the proliferation of bronchial vessels and precapillary anastomoses with the pulmonary circulation (Figs 19.1 and 19.2). These enlarged

vessels are susceptible to injury from the local inflammation and frequent episodes of infection that are the hallmark of bronchiectasis.[137]

Tuberculosis (TB) and its sequelae, such as bronchiectasis, broncholithiasis and recurrent bacterial infections continue to remain the most common causes of hemoptysis in the developing world.[4] Hemoptysis tends to develop in young, female patients with extensive disease, in cases of TB relapse, and in patients with old inactive mycobacterial disease complicated by bacterial superinfection.[138] Early pneumonia from tuberculosis may cause scant hemoptysis resulting from the necrosis of a small vessel; however, later stages of the disease may develop severe parenchymal fibroulcerative lesions that can erode into a bulging arterial aneurysm causing episodes of massive bleeding and respiratory distress (Figs 19.3 and 19.4).[139] Also, calcified lymph nodes impinging on the airway can erode into the airway lumen and cause streaky hemoptysis by disrupting vessels in the peribronchial and submucosal plexi; alternatively, they can lead to massive hemoptysis when there is a large bronchial artery in the path of this eroding calcified lymph node or broncholith.[140] Finally, expanding, thick-walled tuberculous cavities may incorporate pulmonary vessels that are prone to damage and bleeding when exposed to inflammation and mycobacteria. The vessels become ectatic and aneurysmal, as well as may rupture to cause massive hemoptysis.[139,141]

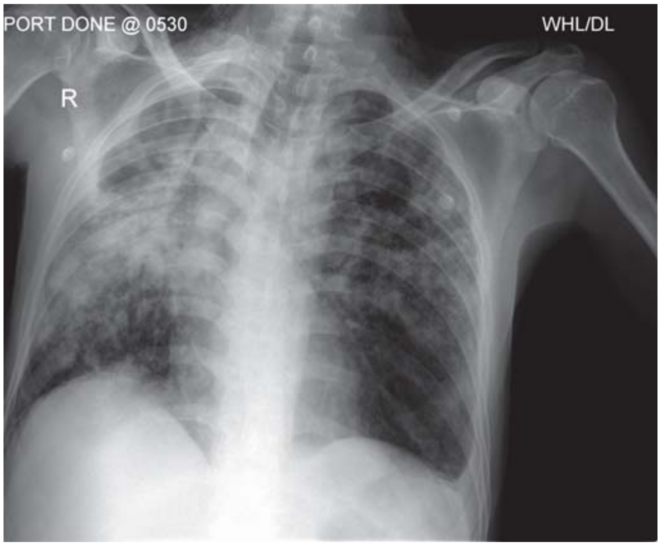

Fig. 19.3: Chest radiograph of patient with active tuberculosis

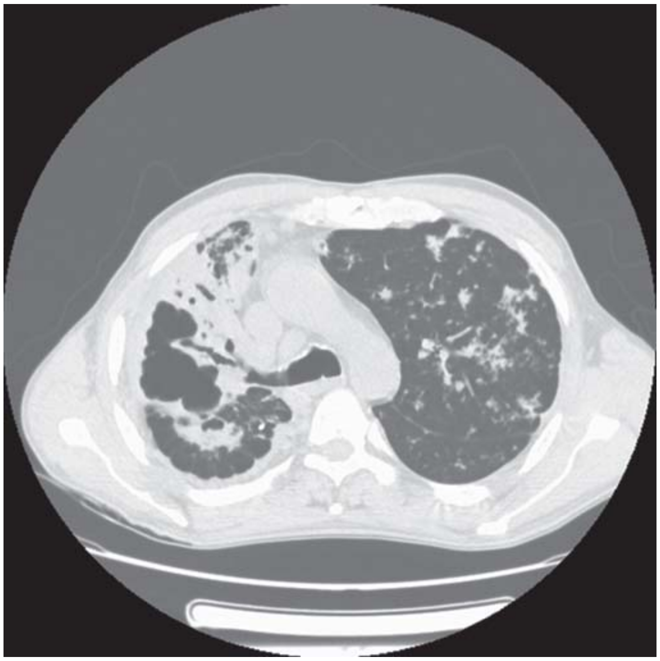

Fig. 19.4: Computed tomography of the chest showing an axial image of a patient with HIV and active tuberculosis

Cavities may develop in pulmonary parenchyma damaged by TB, sarcoidosis, vasculitis, emphysema, neoplasms, pulmonary fibrosis, lung abscess, bronchial cyst, asbestosis, ankylosing spondylitis or pulmonary infarction.[142] These pre-existing cavities may become colonized by aspergillus to form mycetomas or fungus balls (Fig. 19.5). These mycetomas are frequently complicated by hemoptysis, up to 85% of the time.[31,143] The fungus ball may cause erosion into a blood vessel by releasing anticoagulant proteolytic enzymes.[144,145]

Melioidosis caused by *Burkholderia pseudomallei* may mimic active tuberculosis. Most cases have been reported in Southeast Asia. Melioidosis, like active tuberculosis, causes protean signs and symptoms that include fever, productive cough, hemoptysis, weight loss, pleuritic chest pain and, typically, necrotizing upper lobe involvement. The disease can also be present acutely with an abrupt onset and rapidly deteriorating course.

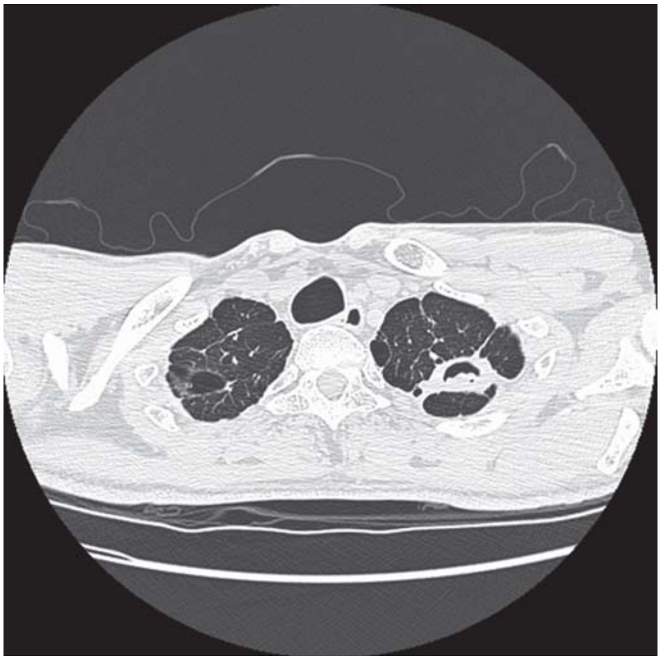

Fig. 19.5: Computed tomography of the chest showing an axial image of a patient with a mycetoma in a preformed cavity secondary to sarcoidosis

Recrudescence has been described up to 26 years after the patient had left the endemic zone.[146]

The ingestion of raw or undercooked shellfish primarily in Southeast Asia may lead to infection with *Paragonimus westermani*. The adult parasite forms cysts near bronchioles and bronchi. Hemoptysis occurs as the cysts erode into the airway.[44,45] Loeffler's syndrome is caused by different types of parasites (e.g. Ascaris, hookworm, Strongyloides) due to the migration of parasite larva through the lungs, most often one to two weeks after infection, but the incubation period will vary depending on the species of the parasite.[147] The syndrome is characterized by fever, urticaria, wheeze, dry cough and sometimes, hemoptysis. Typically, the patient has eosinophilia on a complete blood count and the chest radiograph shows migratory pulmonary infiltrates.

Neoplastic Causes

Bronchogenic carcinoma may present with hemoptysis when the tumor invades a blood vessel or becomes necrotic. Hemoptysis can be the presenting symptom in 10% of lung cancer patients,[57] typically mild to moderate.[148] Squamous cell carcinoma seems to be the most likely type of lung cancer to cause massive bleeding because of its typical central location and tendency to cavitate.[57] Squamous cell carcinoma is 10 times more likely to bleed than other types of bronchogenic carcinoma (Fig. 19.6).[57] Bronchial carcinoids are slow growing endobronchial neuroendocrine tumors that are highly vascularized and may bleed up to 30% of the time.[149,150]

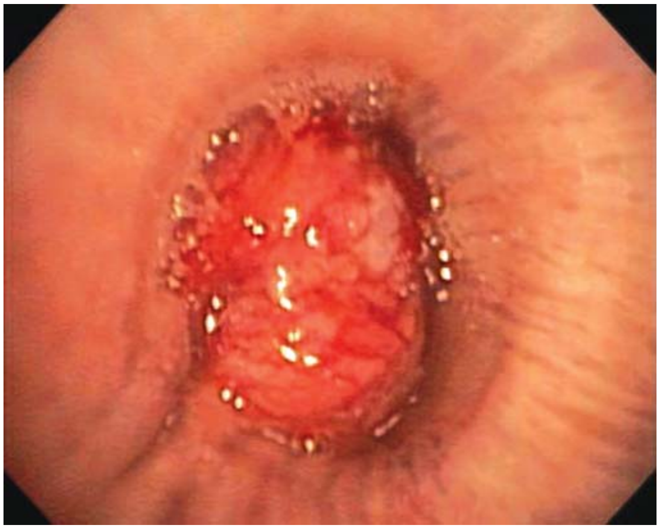

Fig. 19.6: Bronchoscopy picture showing a highly vascularized squamous cell lung carcinoma

Cardiac Causes

The elevated pressure in the pulmonary circulation that results from congestive heart failure and mitral stenosis may lead to the distension and rupture of pulmonary and bronchial veins. Significant back pressure from mitral stenosis may be transmitted to the bronchial veins, resulting in submucosal varices that are prone to rupture and bleeding.[151,152]

Vascular Causes

Venous thromboembolism can cause hemoptysis when there is the necrosis of pulmonary parenchyma due to infarction, congestive atelectasis or hemorrhagic consolidation. Venous thromboembolism can also cause hemoptysis by increasing bronchial artery blood flow through collaterals that are formed with the pulmonary circulation to bypass the embolized artery.[153,154]

Pulmonary arteriovenous malformation (AVM) is another important cause of hemoptysis that may result in profuse bleeding. The majority of hemoptysis caused by AVMs will be seen in the patients with hereditary hemorrhagic telangiectasia or Osler-Weber-Rendu syndrome. The AVMs tend to be numerous and bilateral, bleeding occurs from either rupture of a pulmonary AVM or an endobronchial telangiectasia.[7] The risk of bleeding is higher with feeding vessels of > 3 mm.[158]

Dieulafoy's lesion is another type of vascular malformation. In these lesions, there is a bronchial artery draining into a pulmonary artery causing left-to-right shunting of blood. Dieulafoy's disease of the bronchus is associated with the abnormal superficial location of this vascular anomaly contiguous to the epithelium of the bronchial mucosa. Dieulafoy's lesions can appear as sessile tumors covered by endobronchial mucosa or they may have an overlying white cap. If biopsied, these lesions may bleed profusely.[159] Disease of the bronchus is analogous to the Dieulafoy's lesion of the gastric mucosa that can present with severe upper gastrointestinal bleeding due to the superficial location of a dilated, ectopic gastric artery.

Congenital Causes

Cystic fibrosis patients are prone to develop pulmonary abscesses, recurrent pneumonias and bronchiectasis (Figs 19.1 and 19.2). Patients may subsequently present with hemoptysis, the risk appears to increase with more advanced age.[160,161] Bronchiectatic airways bleed because they have a higher degree of vascularity in the endobronchial and peribronchial circulation.[80]

Trauma

Both penetrating and blunt chest trauma can cause hemoptysis. Pulmonary lacerations, pneumatoceles and pulmonary hematomas may all be caused by blunt chest trauma. Pulmonary contusions occur when external forces are applied to the pulmonary parenchyma. Pulmonary contusions cause the disruption of the alveolar-capillary membranes, increased permeability and edema, shunting and ventilation-perfusion mismatching. Pulmonary contusions rarely cause hemoptysis since they do not tend to disrupt the pulmonary parenchyma and the bleeding is confined to the alveoli and interstitium.[84] Tracheobronchial injury is another type of traumatic injury that may occur with the sudden compression of the chest and shearing of the mainstem bronchus. Chest compression against a closed glottis can also tear the membranous portion of the cartilaginous rings and cause hemoptysis. Deceleration injuries may cause rupture at fixed points at the cricoid and main carina.[162]

Iatrogenic Causes

Rupture of the pulmonary artery by a balloon flotation catheter may complicate right heart catheterization. This complication tends to occur when there is pulmonary hypertension, a distally located catheter tip, excessive catheter manipulation, a large catheter loop in the right ventricle or advanced age.[25]

Tracheoarterial fistulas usually involving the innominate artery, are complications of tracheotomies and a cause of life-threatening hemoptysis. The fistulas are most likely to form at the stoma in low tracheotomies, at the balloon site, or at the tip of the tracheotomy tube when there is excessive angulation causing pressure necrosis. It usually takes at least 48 hours after tracheotomy to develop a tracheoarterial fistula. A sentinel bleed precedes massive hemoptysis in 35 to 50% of these cases.[91]

Transbronchial lung biopsies may cause hemoptysis in 2% of cases, the bleeding is usually mild and self limited. However, some patients are at a higher risk of more profuse bleeding, especially those with thrombocytopenia and uremia, those who are immunocompromised, or those who are on mechanical ventilation.[163] Caution should also be taken when performing transbronchial biopsies in patients with severe pulmonary hypertension [pulmonary artery systolic pressure (PASP) > 55-60 mm Hg] as they may be at increased risk for bleeding complications.[164,165]

Systemic and Immune Diseases

Diffuse alveolar hemorrhage (DAH) may occur due to capillary damage by autoimmune diseases, such as Goodpasture's syndrome; Systemic lupus erythematosus (SLE); the ANCA-associated vasculitides [Necrotizing granulomatous vasculitis (NGV), (formerly Wegener's granulomatosis)], microscopic polyangiitis; Churg-Strauss syndrome; and cryoglobulinemia (Figs 19.7 and 19.8). All of these diseases may involve the nervous system, gastrointestinal tract, skin, kidneys and joints.[166-170] Thoracic endometriosis is the cause of catamenial hemoptysis, happening within 48-72 hours of menses.[171]

Drugs/Toxins

Anticoagulants and thrombolytics may induce hemoptysis in patients with underlying chronic inflammation (e.g. chronic bronchitis), neoplastic lesions, or structural abnormalities of the lungs and airways (e.g. bronchiectasis).[172] Other, rare causes of toxin-induced DAH and hemoptysis include penicillamine, mitomycin-C, isocyanates, crack cocaine, abciximab, sirolimus, all-trans-retinoic acid and trimellitic anhydride.[120,122,173,174]

Cryptogenic Hemoptysis

Cryptogenic or idiopathic hemoptysis is the term used when no specific cause of hemoptysis can be found after

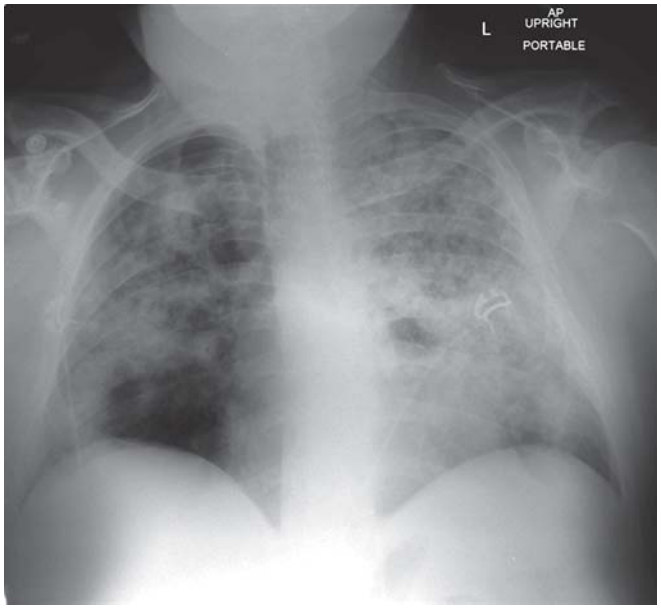

Fig. 19.7: Chest radiograph of a patient with diffuse alveolar hemorrhage in the setting of necrotizing granulomatous vasculitis

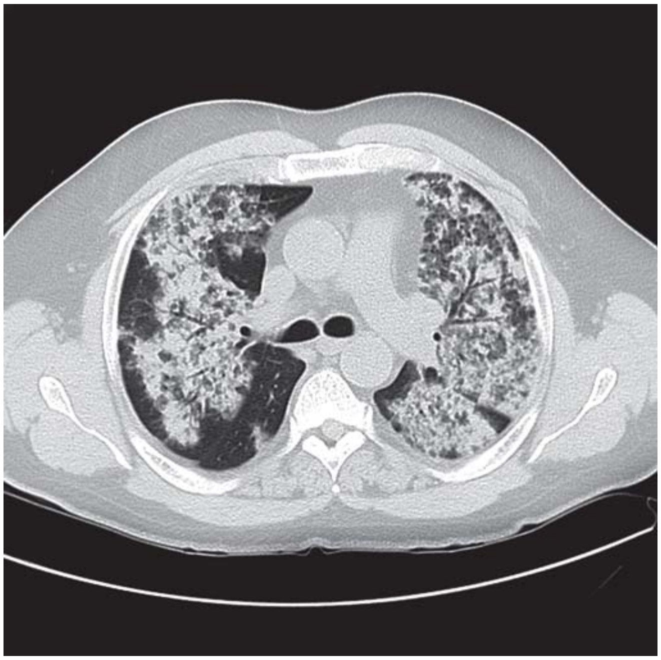

Fig. 19.8: Computed tomography of the chest showing an axial image of a patient with diffuse alveolar hemorrhage in the setting of necrotizing granulomatous vasculitis

thorough medical, roentgenographic and bronchoscopic evaluations. The incidence at referral centers is about 19%. In general, the prognosis for cryptogenic hemoptysis is favorable with the resolution of any further hemoptysis within six months of the initial evaluation. However, more contemporary data over a 6.6 year period of follow-up, has revealed that the subsequent diagnosis of lung cancer in patients with cryptogenic hemoptysis may be as high as 6%, especially among those patients who smoke and are older than 40 years of age.[124] Interestingly, it was found in a recent report from France, which described 81 patients who were labeled as cryptogenic hemoptysis, that five out of the nine patients in the cohort who presented with massive hemoptysis and required surgical intervention had a Dieulafoy's lesion as the etiology, discovered on surgical specimens. These patients were all smokers and it is postulated that the associated chronic irritation and inflammation from smoking may have participated in the pathological evolution of the ectopically located, superficial bronchial arteries seen in Dieulafoy's disease of the bronchus.[175]

Diagnostic Approach

If one excludes cryptogenic hemoptysis as a distinct diagnosis, the cause of hemoptysis can be determined in 68 to 98% of cases.[15,176] The diagnostic work-up of hemoptysis involves both standard evaluations that should be performed on most patients (Table 19.3), and specialized testing to be ordered only if indicated by the specific clinical setting (Table 19.4). After the initial evaluation, the next steps are determined by each patient's specific clinical picture.

- Stool exam for ova and parasites

Pathology
- Lung or kidney biopsies

History

A detailed history and physical examination should always be performed (Table 19.3). The first step is to confirm the presence of hemoptysis and distinguish it from pseudohemoptysis. The second step is to try to quantify the volume of hemoptysis. The third step involves identifying the most likely broad category of etiology (Table 19.1). The fourth and final step is to find a specific cause of hemoptysis.

Even though not indicative of severity, the frequency, timing and duration of hemoptysis may be helpful in assessing the cause of hemoptysis. Bronchiectasis may present with recurrent episodes over the course of years.[177] Bronchogenic carcinoma causes the recurrent episodes of mild hemoptysis often developing for a few weeks.[178] The timing can also be misleading in a patient with chronic bronchitis who may subsequently develop a lung cancer. Hemoptysis coinciding with menstrual period, suggests thoracic endometriosis.[171] Exertion induced and post-coital bloody expectoration is characteristic of pulmonary congestion as seen with cardiogenic pulmonary edema.[68] Acute onset of hemoptysis, fever and chest pain suggests infection or pulmonary infarction from thromboembolism.[1]

The patient's age is another important consideration. Before the third decade of life, the likely causes of hemoptysis include acute tracheobronchitis, congenital cardiac or pulmonary disease, cystic fibrosis and infectious pneumonia. However, persistent hemoptysis after adequately treated pneumonia should raise the suspicion of an endobronchial lesion or a coagulopathy.[179] Bronchogenic carcinoma is very rare in patients younger than 40 years of age; however, germ cell tumors may lead to endobronchial metastases that may bleed. Bronchial adenoma is another consideration in the younger patient population.

Occasionally, the character of the sputum can add some useful information during the diagnostic evaluation. Pulmonary edema from passive congestion, as seen with left ventricular failure and mitral stenosis, may present with pink frothy sputum in a patient with orthopnea and paroxysmal nocturnal dyspnea. When gritty, white material is seen mixed with blood in the sputum, one should consider the diagnosis of broncholithiasis as seen in tuberculosis and histoplasmosis. Blood and pus in expectorated sputum suggest infection.

A history of hematuria should raise the suspicion of a vasculitis. NGV comes with the characteristic triad of upper and lower airway disease with rapidly progressive glomerulonephritis. SLE may cause DAH anytime during the course of the disease.[106] When the pulmonary and renal manifestations are present in a young male smoker, Goodpasture's syndrome, caused by antibasement membrane antibodies, is a strong possibility;[97] influenza infection,[180] inhalation of hydrocarbons,[181] and penicillamine ingestion should also be considered.[120] DAH may also complicate hematopoietic stem cell transplantation in 5% of allogeneic and autologous recipients, and in this setting, carries a 50 to 100% mortality rate, with a 38% six-month mortality rate for those who survive.[182]

Hemoptysis with simultaneous bleeding from the gastrointestinal tract, skin or the nose may point to an inappropriate high dose of anticoagulants or a bleeding disorder such as Disseminated Intravascular Coagulation (DIC). The latter should be suspected in a critically ill patient with bleeding, thrombocytopenia and microangiopathic anemia. Oral contraceptives, prolonged immobilization, long bone fractures and recent surgery should raise the suspicion of deep venous thrombosis and venous thromboembolism.

Tracheoarterial fistulas, though rare, should be considered in a patient with a tracheotomy and hemoptysis. Massive hemoptysis from rupture of these fistulas will have a sentinel or preceding smaller bleed in 34 to 50% of cases. The peak incidence is between the first and second week after tracheotomy, with 72% occurring within 21 days.[91] During the initial 48 hours of tracheotomy placement, bleeding can result from overly vigorous suctioning.

The travel history should be documented. Bacterial, fungal and parasitic etiologies for hemoptysis can be suspected depending on the geographical area of exposure. Tuberculosis is endemic in the developing world and should always be considered in the differential diagnosis. Melioidosis caused by *Burkholderia pseudomallei* is ubiquitous in the soil and stagnant water of Southeast Asia, as well as it can mimic the clinical presentation and course of tuberculosis.[146] Examples of fungal infections include coccidiomycosis in the Southwest of the United States, Central and South America; histoplasmosis in the Mississippi River valley, as well as in the caves of South America and Africa; and paracoccidiomycosis in the regions of North, Central and South America. Examples of parasitic infections include paragonimiasis in travelers to East Asia, Central and South America, Central and West Africa; and schistosomiasis in all of Africa, the Middle East, Southeast and Central Asia and South America.[147]

Physical Examination

While doing a physical examination, special attention should be paid to the nose, gums, pharynx and skin. The presence of telangiectasia suggests a diagnosis of Osler-Weber-Rendu disease. NGV will frequently involve the nasal passages. Ecchymoses and petechiae raise the concern for a clotting disorder or a vasculitic process. When wheezing is localized, it points to an endobronchial lesion. Stridor is more likely seen with an obstructing lesion of the extrathoracic airway or edema of the larynx. Localized crackles suggest focal airspace disease. Even though the physical examination may be helpful in determining the cause of hemoptysis, it is unreliable in localizing the site of bleeding.[6]

Laboratory Evaluation

Routine laboratory studies may be helpful in specific situations. Iron deficiency anemia may suggest idiopathic pulmonary hemosiderosis; likewise, an elevated white blood cell count in the right clinical setting may support a diagnosis of pneumonia. The urinalysis may show hematuria as seen with the pulmonary - renal syndromes. Coagulation studies and platelet counts may unmask a bleeding disorder. The Brain Natriuretic Peptide (BNP) may aid in the diagnosis of cardiogenic pulmonary edema.

Sputum Gram stain and cultures may aid in the diagnosis of bacterial pneumonia. Acid-fast bacilli smear and cultures can also be obtained from sputum. Serum anti-glomerular membrane antibodies help in the diagnosis of Goodpasture's, antineutrophil antibodies and antineutrophil cytoplasmic antibodies (ANCA) will be elevated in SLE and NGV, respectively.

Chest Radiograph

An initial posteroanterior and lateral chest radiograph should always be obtained in patients with hemoptysis. About 30% of patients with hemoptysis will have a normal chest radiograph.[183-186] The chest radiograph may sometimes reveal bilateral lesions and the source of hemoptysis will not be localized in up to 40% of patients.[6] Aspirated blood may give a false impression of being the source of hemoptysis, and bronchoscopy may reveal other areas causing bleeding that were not evident on the chest radiograph.[104,187,188] The chest radiograph may reveal radiopaque foreign bodies that can cause hemoptysis even years after aspiration. Cavities may be single or several, suggest tuberculosis and other bacterial, fungal or parasitic infections, thromboembolic events, neoplasms or NGV (Figs 19.7 and 19.8). The finding of a mass within a preformed cavity is suggestive of a fungus ball, seen with aspergillomas. Squamous cell lung carcinoma is the most likely type of lung cancer to cavitate (Fig. 19.6). Multiple nodules are seen in septic emboli, miliary TB, lung metastases and NGV. Arterio-venous fistulas may be seen as pulmonary nodules with feeding vessels. Diffuse alveolar filling, sparing the costophrenic angles and apices, is suggestive of pulmonary hemorrhage. Thick, dilated bronchi with an air fluid level may be seen in bronchiectasis. Bilateral pleural effusions, an enlarged cardiac silhouette, Kerley B lines and perihilar edema suggest congestive heart failure.

Bronchoscopy

Bronchoscopy is a very valuable tool for localizing and diagnosing the source of hemoptysis, but not all patients with hemoptysis require a bronchoscopy. Patients who may forgo this procedure include those with strong evidence of a non-neoplastic disease (e.g. congestive heart failure), those with pseudohemoptysis, those whose condition is so debilitating or so far advanced that no change in management will result from the bronchoscopic findings, and lastly those who are younger than 40 years of age with short-lived hemoptysis of less than one week in duration.[183]

Bronchoscopy will localize the source of bleeding in 93% of patients if performed within 24 hours.[187,189] However, the rate of success drops to 51% if done within 48 hours.[190] Rigid bronchoscopy is preferred in the cases of massive hemoptysis because an airway is secured and the patient is ventilated during this procedure. The rigid bronchoscope has a large lumen that allows for more vigorous suctioning and more therapeutic options than a flexible bronchoscope. Rigid bronchoscopy must be performed under general anesthesia in the operating room. Flexible bronchoscopy may be performed at the bedside, does not require general anesthesia, and can visualize up to the sixth generation of airways. However, the suctioning capacity of the flexible bronchoscope is limited and it does not secure the airway. To deal with this problem, the patient can be intubated and the bronchoscope advanced through the endotracheal tube. This ensures airway control and makes frequent removal and reinsertion of the bronchoscope possible. Alternatively, the patient could be intubated with a rigid bronchoscope for better suctioning and a flexible bronchoscope can be advanced through it for better overall airway visualization.

Bronchoscopy may also be helpful in the diagnosis of DAH. Bronchoalveolar lavage fluid that becomes progressively bloodier with each aliquot and lavage fluid containing hemosiderin-laden macrophages that number more than 20% of total alveolar macrophages are both suggestive of DAH.[191]

Computed Tomography

Computed Tomography (CT) scanning plays an important role in the evaluation of hemoptysis. It has been shown, in some studies, to be as good as bronchoscopy for localizing the bleeding, and superior to bronchoscopy at diagnosing the cause of bleeding.[192] Chest CT is superior to plain films and bronchoscopy in diagnosing bronchiectasis, post-tuberculous lesions, aspergillomas and tumors, together the most common causes of massive hemoptysis. However, CT will fail to identify localized mucosal abnormalities such as bronchitis, telangiectasias, early carcinoma, squamous metaplasia, benign papillomas and Kaposi's sarcoma.[190] Contrast administration appears to be unnecessary for making a diagnosis by CT. In addition, a large number of patients with massive hemoptysis will undergo angiographic embolization. It seems appropriate to consider a CT of the chest without contrast on all cases of massive and moderate hemoptysis.[192]

Bronchial Angiography

Bronchial angiography is an excellent method for localizing the site of bleeding in patients with active, submassive and massive hemoptysis. Abnormal bronchial arteries may be hypertrophied, tortuous, increased in size and number, as well as there may be arteriovenous shunts and aneurysms.[193] The site of bleeding can be determined angiographically in up to 90 to 93% of cases.[194] Angiography may locate a bleeding site in about 4% of cases, when bronchoscopy and other radiographic techniques fail.[189] Once a bleeding vessel is identified, arterial embolization can be performed to stop the bleeding; potential therapeutic intervention represents an additional advantage of arterial angiography (Figs 19. 9 and 19.10).

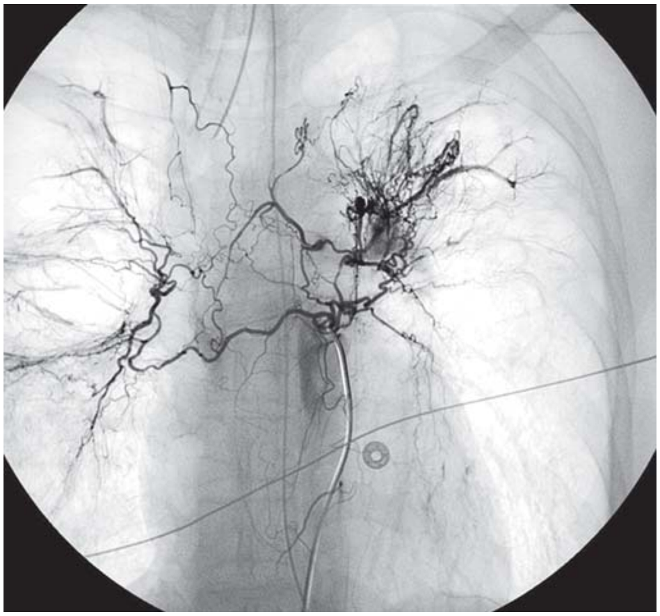

Fig. 19.9: Selective bronchial angiography showing intense neovascularization and bronchial-pulmonary anastomoses in a patient with a left upper lobe mycetoma

TREATMENT

The goals of treatment are to prevent asphyxiation due to the aspiration of large volumes of blood and to stop the bleeding. Both general supportive care and more specific definitive measures are necessary. Figure 19.11 shows an overview of the therapeutic approach to hemoptysis.

Supportive Care

Patients should be placed on bed rest; if the site of bleeding is known, the affected lung should be placed down in the lateral supine position. Mild sedation can be used to attenuate vigorous coughing that may worsen bleeding by dislodging clots; however, too much depression of cough should be avoided because an effective cough may be necessary to avoid aspiration and

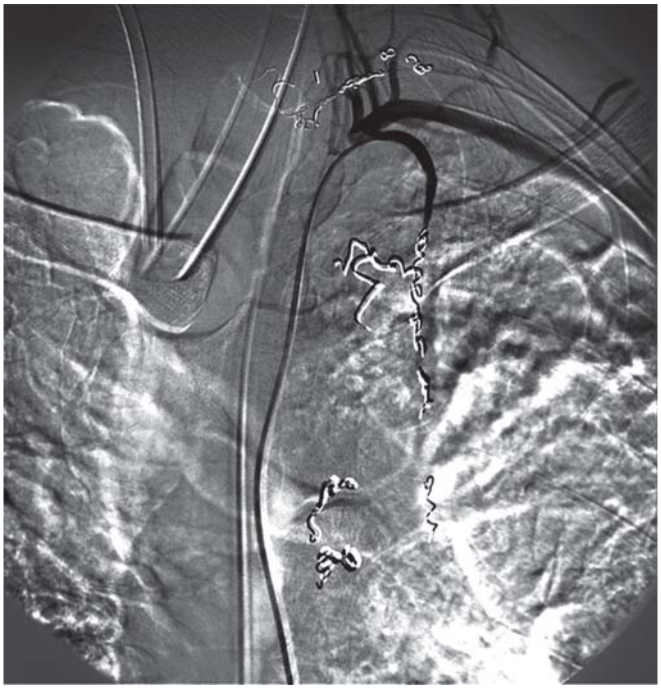

Fig. 19.10: Angiographic coil embolization of internal mammary artery and thyrocervical artery branches. Notice the acute cutoff of the contrast in the internal mammary artery after the coils

asphyxiation. Chest physiotherapy and postural drainage should be avoided.

Patients who experience rapid deterioration with worsening oxygenation may require endotracheal intubation. Whenever intubation is needed, an 8.0 mm or greater endotracheal tube should be used to allow for future bronchoscopy. Another option is to intubate with a double lumen tube and try to isolate the unaffected lung; however, these tubes have a smaller internal diameter that can be more easily obstructed by clots and secretions. They are also difficult tubes to place properly, even by an experienced anesthesiologist, are prone to migrate and lose their isolating effect.[11] Intravenous (IV) fluids and blood products should be administered as needed to reverse any underlying coagulopathy; two large bore peripheral IV lines should be placed for this end. An exception to the avoidance of anticoagulation is patients with venous thromboembolism.[195]

Definitive Care

Nonmassive Hemoptysis

For the definitive care of nonmassive hemoptysis, treatment should be targeted to the specific underlying cause. Suppurative bronchiectasis should be treated with antibiotics and a bronchodilator (e.g. β-adrenergic agonists). Similarly, an exacerbation of chronic bronchitis can be controlled with steroids, antibiotics and a bronchodilator; but most importantly, by smoking cessation. Airway lesions should be resected whenever possible. Congestive heart failure and mitral stenosis can be treated with diuretics and afterload reduction. Venous thromboembolism should be treated with anticoagulation and diuretics.

Massive Hemoptysis

Several bronchoscopic options are available to stop severe bleeding. Placement of an endobronchial balloon can be used for tamponade in all lobes except the right upper lobe where the acute angle of the right upper lobe bronchus prevents placement.[196] Placement is done with a 100 cm long four French Fogarty balloon catheter. The balloon should be positioned in a way that completely occludes the bronchus and causes distal pulmonary collapse. Smaller catheter balloons can also be used and be placed more distally in segmental bronchi. Other interventions include iced saline lavage, laser bronchoscopy,[196] application of topical epinephrine (1:20,000), thrombin, or a fibrinogen-thrombin combination.[197]

Angiographic embolization has a high success rate for the control of massive hemoptysis, being successful in 77 to 95% of cases (Figs 19.10 and 19.11).[21,189] However; there is a 16% incidence of rebleeding within one to four days so multiple procedures are frequently necessary.[21,198,199] After proper control of hemoptysis, it may be expected that 20% of patients will rebleed in the next six months,[200] and 22% within three to five years.[21] The potential complications of angiographic embolization are rare, but spinal artery embolization does occur less than 1% in experienced hands of the time, especially when a spinal artery originates from a bronchial artery.[198]

The role of surgery has decreased significantly due to the high success rate of angiographic embolization procedures. However, surgery remains the preferred treatment of massive hemoptysis a arteriovenous malformations, leaky aortic aneurysms, hydatid cysts, pulmonary artery ruptures, chest traumas, bronchial adenomas and fungus balls that have not responded to medical therapy.[198] All these situations involve either a problem not amenable to embolization, or a very likely recurrence after embolization.

The treatment of DAH generally requires intravenous corticosteroids, cytotoxic drugs and even plasmapheresis (e.g. NGV and Goodpasture's). Vasculitis-induced DAH

will often require combined therapy. Pulmonary aspergillomas have been treated by the intracavitary instillation of amphotericin B, nystatin and sodium iodide solutions.[201,202] Local radiation of fungus balls may be an alternative for patients too debilitated or having such a poor pulmonary reserve that surgery is high risk.[203,204]

When bleeding is due to a tracheoarterial fistula, immediate measures should be taken to prevent exsanguination. One way to try to tamponade the bleeding vessel in an acute emergency consists of over-inflating the balloon cuff of the tracheotomy tube as downward and forward pressure is applied on top of the tracheotomy tube. If bleeding slows down with this maneuver, an endotracheal tube should be placed distal to the tip of the tracheotomy tube and a surgical consult should be requested emergently.[91]

In the presence of iatrogenic pulmonary artery rupture, the Swan-Ganz catheter may be withdrawn 5 cm with the balloon deflated; the balloon is then reinflated and allowed to float back to tamponade the bleeding vessel. The patient should also be intubated in the mainstem bronchus of the contralateral lung. If bleeding is controlled, patients should immediately undergo pulmonary angiography to localize the arterial tear and assess for the formation of a pseudoaneurysm. Frequently, embolization can be performed at the same time.[25]

In summary, hemoptysis is an important symptom requiring a thorough medical evaluation to determine the underlying diagnosis. The first step in evaluation is a complete medical history and physical examination. Depending on whether the bleed is massive or non-massive, subsequent evaluation and treatment may require additional radiographic imaging, flexible bronchoscopy, rigid bronchoscopy, angiographic embolization and surgery. The diagnostic tests and therapeutic interventions required will depend largely on the clinical presentation, rate of bleeding, and the availability of the proper equipment and experienced personnel.

Dyspnea

J Mark Madison, Richard S Irwin

INTRODUCTION

Dyspnea is difficult, labored or unpleasant breathing that is distressing to an individual.[1] The symptom of dyspnea, often referred to as shortness of breath, is frequently described vaguely by patients and it is probably not a single sensation given the many qualitative descriptors patients use to describe it. Three distinct sensations of respiratory discomfort have been described to subcategorize dyspnea—air hunger, work and effort related, and chest tightness—and it is possible that different neural pathways underlie each.[2]

PHYSIOLOGY

The physiologic basis of dyspnea is not yet established. However, because the cardiorespiratory system is complex and regulated by complex neurophysiology, it is likely that multiple different sensory, efferent, brain stem and cortical neural pathways are involved in mediating the sensation of dyspnea.[1-3] Afferent neural pathways from all thoracic and even upper abdominal organs may potentially modulate or mediate the sensation of dyspnea.[2,4] It is not surprising that many cardiopulmonary disorders can result in dyspnea or that the intensity of the sensation can be modulated by learning, experience, and emotional and behavioral conditions.

Evidence suggests that three different types of neural receptors are involved in the genesis of dyspnea: chemoreceptors, mechanoreceptors and ergoreceptors of skeletal muscle.[5] Afferent signals from these receptors are integrated in the central nervous system, modulated by cortical input, and compared to efferent motor neuron discharge to the respiratory muscles.

Chemoreceptors detect changes in blood carbon dioxide and oxygen levels.[5] Acute increases in arterial carbon dioxide potently stimulate medullary chemoreceptors that lead to dyspnea by increasing ventilation and by mechanisms independent of ventilation as well. The effect of carbon dioxide on these central chemoreceptors is probably indirect and due to changes in pH. Consistent with this, patients with chronic hypercapnia and a compensated respiratory acidosis are less dyspneic at the same partial pressure of carbon dioxide and less sensitive to changes in carbon dioxide as well. Peripheral chemoreceptors in the carotid and aortic bodies are stimulated by decreases in the partial pressure of oxygen in arterial blood and to a lesser extent by increases in carbon dioxide and decreases in pH. Although it would intuitively seem that hypoxemia would be the main stimulus to dyspnea, this has not been supported by clinical observation or experimental evidence. Not all subjects with dyspnea have hypoxemia and not all patients with hypoxemia have dyspnea. Instead, low oxygen is not the main stimulus to dyspnea and is a much less potent stimulus than elevated carbon dioxide. Evidence suggests that, although it is not a potent stimulus, low oxygen does contribute to dyspnea mainly through its effects on increased ventilation.

Mechanoreceptors are neural receptors that detect changes in pressure, stretch and position.[5] The respiratory system has many different types of mechanoreceptors located throughout the airways, lung parenchyma, chest wall and diaphragm. Discordance between the afferent output of these mechanoreceptors and respiratory motor efferent discharge is believed to play a central role in generating the distressing sense that breathing is difficult.[2]

Ergoreceptors (also called metaboreceptors) are believed to underlie the ergoreflex.[5] This is a complex metabolic reflex that originates in skeletal muscles and stimulates ventilation. Ergoreceptors in skeletal muscle are thought to detect metabolic products of active muscle (possibly lactic acid and others) and send afferent signals that stimulate ventilation. There is high research interest in this reflex and its metabolic receptors, particularly the role of the reflex in causing dyspnea in the settings of heart failure and Chronic Obstructive Pulmonary Disease (COPD).

Differential Diagnosis of Dyspnea

The causes of dyspnea are numerous. Many diseases and disorders of the cardiorespiratory system and other organ systems can result in dyspnea. However, the causes of dyspnea can be categorized into general areas (Table 20.1). The frequency with which specific causes of dyspnea are encountered will vary with the clinical setting, the acuity of onset, and the age of the patients. For different clinical settings, it has been estimated that 75 to 92% of cases of dyspnea in an emergency department or inpatient hospital setting are due to cardiopulmonary diseases and disorders, while in the ambulatory setting that figure is 46 to 85%.[1, 6-9] Pulmonary, cardiac, psychogenic, Gastroesophageal Reflux Disease (GERD) and deconditioning disorders were the most common causes in an ambulatory clinic specializing in pulmonary diseases[9] (Fig. 20.1). Specifically for chronic dyspnea, the four most common causes were COPD, asthma, interstitial lung disease and cardiomyopathy.[8]

Disease-Specific Pathophysiology

The pathophysiologic mechanisms underlying dyspnea in asthma, COPD, cardiac disorders, GERD, psychogenic disorders and deconditioning are different and not well established.[3]

Respiratory mechanical factors, arterial blood gases and psychological factors all contribute to the genesis of dyspnea in asthma. Importantly, the severity of dyspnea in asthma does not always correlate with the degree of airway obstruction. Asthma patients with a prior history of near-fatal exacerbations have a decreased ventilatory response to hypoxia and a decreased sense of dyspnea.[10] In COPD, respiratory mechanics play an important role similar to that in asthma. However, the role of carbon dioxide and hypoxemia in the genesis of dyspnea appears

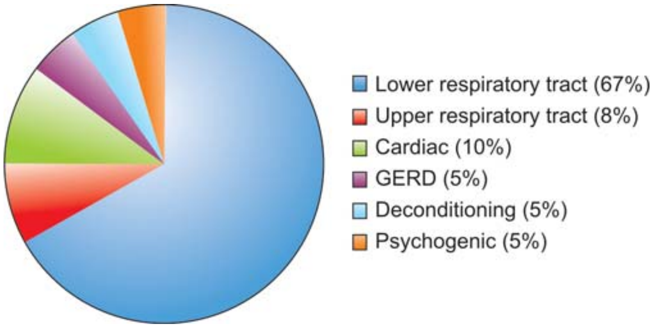

Fig. 20.1: Spectrum and frequency of the causes of unexplained dyspnea. Adapted from reference 9. In this study, 85 patients referred to a pulmonary clinic for difficult to diagnose dyspnea were evaluated. Asthma, chronic obstructive pulmonary disease, interstitial lung disease, and cardiomyopathy accounted for approximately two-third of the cases

to be greater in COPD than in asthma. Recently, for COPD, many studies have focused on the important role that dynamic hyperinflation plays in the genesis of dyspnea during exertion. The dynamic hyperinflation causes increased load on inspiratory muscles, places inspiratory muscles at the suboptimal length for effective contraction, restricts the ability of the patient to increase tidal volume (inspiratory capacity is decreased), and causes ventilation perfusion inequalities that impair gas exchange.[2] Afferent signals from mechanoreceptors and chemoreceptors reflect these distortions of muscle mechanics and changes in gas exchange. Because these are discordant with the amount of efferent motor activity emanating from the medulla respiratory center, severe dyspnea results.[2,11]

Interstitial lung diseases probably cause dyspnea by the mechanical effects of the disease on lung compliance, activation of vagal afferents, and abnormal gas exchange.[1,3] Similarly, compressing lung tissue with pneumothorax or pleural effusion and distortions of the thoracic cage by disease processes (e.g. kyphoscoliosis) probably stimulate dyspnea by the way of vagal afferents, changes in thoracic compliance, and alterations of gas exchange.

Nonpulmonary disorders cause dyspnea by mechanisms that also involve the activation of vagal afferents. Congestive heart failure probably causes dyspnea by the activation of vagal afferent mechanoreceptors in the lungs and airways and by altering gas exchange. How GERD causes dyspnea is not known, but GERD is commonly associated with respiratory symptoms and has been reported to account for unexplained dyspnea, in up to 5% of cases.[1,9,12,13] Possibly, GERD causes dyspnea by the activation of vagal afferents in the esophagus that secondarily stimulate an increase in minute ventilation to produce the sensation of dyspnea.[14] Of course, in severe GERD, the obstructive effects of laryngospasm or the aspiration of refluxate into the lungs would also be expected to contribute to dyspnea. Deconditioning can stimulate dyspnea by requiring increased minute ventilation for the task performed. Finally, there are psychogenic causes of dyspnea, such as anxiety, panic and hyperventilation. Presumably, dyspnea in these conditions is primarily due to the inappropriate cortical modulation of the neural pathways that integrate and compare the normal afferent and efferent activity driving respiration. However, hyperventilation can lead to the alterations of blood gases and these changes may secondarily contribute as well.

POSITIONAL AND NOCTURNAL DYSPNEA

Trepopnea is dyspnea that increases when one side is dependent. For example, patients with a paralyzed hemidiaphragm may complain that they cannot lie down on one side. However, trepopnea is a nonspecific finding because any asymmetric lung disease can cause trepopnea.[3] It can be seen in common diseases, such as COPD and congestive heart failure.

Orthopnea is dyspnea worse on recumbency. It is not a symptom or sign that is specific for congestive heart failure.[3] It can be seen in congestive heart failure, COPD or neuromuscular weakness. It does not reliably distinguish the cardiac causes of dyspnea from pulmonary causes.

Platypnea is dyspnea that is worsened by an upright position.[3] Classically, it is observed when there is right to left shunting of blood, either intracardiac[15] or pulmonary parenchymal.[16] For example, patients with cirrhosis can develop pulmonary arteriovenous malformations at the bases of the lungs. As these shunts become more dependent with the upright position and blood flow through them increases, right to left shunting increases when the patient is upright and this causes orthodeoxia (decrease in arterial oxygen tension when the subject goes from a recumbent position to an upright position) and dyspnea. However, the finding is not specific for right to left shunting of blood and has been reported with ileus and pericarditis as well.[3]

EVALUATING ACUTE DYSPNEA

In evaluating a patient with acute dyspnea, the first priority is to consider potentially life-threatening conditions, such as pulmonary thromboembolism, acute myocardial ischemia or infarction, congestive heart failure, cardiac arrhythmia, an acute exacerbation of asthma or COPD, pneumothorax, upper airway obstruction, pulmonary edema, and pneumonia.[1,3] A history and physical examination should be done and, based on the findings, further testing ordered as appropriate. Commonly useful tests for the evaluation of acute dyspnea include radiographic imaging, electrocardiogram, measurement of serum B-Type Natriuretic Peptide (BNP), complete blood count, arterial blood gases, spirometry or peak flow measures, and Computed Tomography (CT) angiography or ventilation-perfusion lung scanning, and echocardiography.

EVALUATING CHRONIC DYSPNEA

A systematic approach to diagnosing the underlying cause of dyspnea has been validated in a university hospital, ambulatory or pulmonary clinic.[9] In this setting, respiratory disorders accounted for approximately 75% of cases.

Evaluation begins with medical history and physical examination, concentrating on the anatomy of afferent nerves important in the genesis of dyspnea, especially the vagus nerve that subserves organs of both the thorax and upper abdomen. Also, the focus of the medical history and examination should be on the most common causes of chronic dyspnea, including asthma, COPD, interstitial lung disease and cardiomyopathy. If the initial history and physical examination are not suggestive of these most common diagnoses, additional attention should be directed to the other causes of chronic dyspnea, such as postnasal drip syndrome (now referred to as UACS) and other causes of upper airway obstruction, other respiratory disorders, evidence of deconditioning, psychogenic problems (hyperventilation), and GERD. In practice, the history and physical examination are most helpful in ruling out common diagnoses rather than establishing diagnoses. A history of wheezing or a prior diagnosis of asthma is only 50% predictive of asthma being the cause of the patient's chronic dyspnea. For another example, finding crackles on physical examination has only a modest positive predictive value for interstitial lung disease or congestive heart failure being the cause of dyspnea, but the absence of crackles essentially rules out both with 98% and 92% confidence, respectively.

The clinical impression based on medical history and physical examination is next supported by objective testing beginning with a chest radiograph. Abnormal findings on chest radiograph should be pursued as potential causes of dyspnea. The absence of findings on chest radiograph has a high negative predictive value (91%) in excluding many thoracic disorders capable of causing dyspnea.[9]

After the chest radiograph, additional objective testing is warranted to establish the cause of the patient's dyspnea. Without objective testing beyond history, examination and chest radiograph, diagnoses may be incorrect approximately 33% of the time.[1] Several tests are important in evaluating the causes of chronic dyspnea and most of them are useful because of their high negative predictive values for ruling out specific diagnoses[9] (Table 20.2). For example, spirometry is useful for ruling out COPD with 100% confidence and negative bronchial provocation studies (e.g. methacholine inhalation challenge) are useful for ruling out a diagnosis of symptomatic asthma with nearly 100% confidence.

Cardiopulmonary Exercise Testing (CPET) can be very helpful in identifying the underlying cause of dyspnea.[3,17] Observing the ventilatory responses and

TABLE 20.2: Laboratory tests useful in the evaluation of unexplained dyspnea*

Pulmonary function tests
- Spirometry with flow-volume loops
- Spirometry before and after bronchodilator
- Methacholine inhalation challenge
- Lung volumes
- Diffusing capacity
- Arterial Blood Gas (ABG)
- Pulse oximetry at rest and during exertion
- Maximal inspiratory and expiratory mouth pressures
- Cardiopulmonary exercise testing
- Hyperventilation provocation testing

Radiographic imaging
- Chest radiographs
- Chest and neck Computed Tomography (CT) scans

Noninvasive cardiovascular tests
- Blood B-Type Natriuretic Peptide (BNP)
- D-dimer
- Electrocardiogram
- Echocardiography
- Cardiac stress test

Gastrointestinal testing
- Modified barium swallow
- Barium esophagography and/or 24-hour esophageal pH and impedance monitoring

Invasive testing
- Lung biopsy
- Cardiac catheterization

*For more complete listing and suggested sequence of testing, see reference 3.

changes in gas exchange during exercise can help distinguish cardiac from pulmonary causes of dyspnea, provide evidence of deconditioning, and help identify patients with psychogenic causes of dyspnea.

Normal patients will exercise to their predicted maximum heart rate and, at that point, still have substantial breathing reserve (20 to 40%) compared to their predicted maximum minute ventilation. In cardiac disease, heart rate is maximum at a low workload, there is still substantial pulmonary reserve, the oxygen pulse (oxygen consumption divided by heart rate) is low and the anaerobic threshold is low. Distinguishing a cardiac limitation from deconditioning can be difficult with CPET unless ischemia, arrhythmias, or significant changes in blood pressure are documented by ECG and blood pressure monitoring. Typically, deconditioned patients show a low maximum oxygen consumption and low anaerobic threshold. In contrast, patients with a pulmonary limitation to exercise have a low breathing reserve and do not reach maximum predicted heart rate during exercise. They may show oxygen desaturation, show abnormalities of gas exchange, or have evidence of airway obstruction on postexercise spirometry. Patients with psychogenic dyspnea may have a normal CPET study or, with anxiety/hyperventilation syndromes, demonstrate hyperventilation at rest, but an increase in carbon dioxide as exercise first begins.

Determining the underlying cause of dyspnea depends, whenever possible, on observing that specific therapy eliminates or improves the symptom. Because causes of dyspnea may coexist simultaneously, partially successful therapy should not be discontinued as new therapeutic trials are attempted. Instead, add therapies sequentially.

TREATMENT

Specific

The best treatment of dyspnea is specific treatment directed at the underlying cause of the symptom. In one study, 76% of patients improved with specific therapy.[9] All patients with asthma, UACS, psychogenic causes, deconditioning, or GERD improved with specific therapy. Fewer patients improved with specific therapy for COPD (33%), interstitial lung disease (58%) and cardiomyopathy (78%). It is beyond the scope of this chapter to comprehensively review the treatment of even the most common causes of dyspnea. Readers are referred to the chapters that specifically focus on these diseases.

Specific therapy for obesity/deconditioning, psychogenic causes of dyspnea, and neuromuscular diseases should not be overlooked.[3] For obesity or deconditioning, both respond to diet and exercise. Consultation with a dietician and a regular, daily exercise regimen can decrease dyspnea at maximum treadmill workload, with most patients showing some improvement within three months.[3,18] For the psychogenic causes of dyspnea and hyperventilation syndromes, patients often respond to education, reassurance and breathing retraining strategies.[3,19,20] For panic disorder, many patients are helped by counseling, behavioral breathing strategies, and pharmacological intervention if necessary. For neuromuscular diseases, specific interventions designed to increase muscle effectiveness are available. In quadriplegia and potentially other diseases characterized by muscle weakness, patients may benefit from inspiratory muscle trainers aimed to increase muscle hypertrophy and strength in inspiratory muscles still innervated.[21] For patients with cervical injuries resulting in diaphragm paralysis, diaphragmatic pacing can help. Resting weak muscles with nocturnal or intermittent positive pressure mechanical ventilation may help some patients with severe muscle weakness due to diseases, such as amyotrophic lateral sclerosis or muscular dystrophy.[22]

Nonspecific

Nonspecific therapy is aimed at the symptom rather than the underlying cause of dyspnea.[3] Many nonspecific therapies for dyspnea have been proposed and these include nutritional support;[23] conditioning regimens;[24] stress reduction; teaching coping skills;[25] respiratory muscle training;[26] supplemental oxygen;[27] noninvasive or invasive mechanical ventilation; vagotomy; muscle vibration techniques; acupuncture; and pharmacotherapy[28] with narcotics, anxiolytics, phenothiazines; and furosemide. The efficacy of these various treatments has not been well established with the exception of nutritional support for patients with COPD.[23]

Some recent evidence suggests that inhaled furosemide may relieve exertional dyspnea in healthy subjects and subjects with COPD,[29-31] although the mechanisms are not clear and probably multifactorial.[32] In 20 subjects with COPD, a single dose of inhaled furosemide decreased dyspnea during exercise and exercise endurance time increased by 1.65 minutes.[32] However, the clinical role of inhaled furosemide is not yet established and awaits larger, multicenter trials.

Although benzodiazepines and opiates have roles in treating dyspnea in the terminally ill cancer patients,[33] their roles in the relief of chronic dyspnea are less clear. Benzodiazepines at low doses are prescribed by some physicians to treat intractable, chronic breathlessness, but there is very little clinical evidence to support this practice. Similarly, the use of nebulized opiates to relieve intractable dyspnea has been proposed, but most studies show no benefit.[28,34] There is more evidence supporting the use of low doses of oral opiates.[28,35] In one randomized and controlled 4-day crossover study, 48 patients who mostly had COPD as the cause of intractable dyspnea were given 20 mg of sustained release morphine per 24 hours.[36] There were documented improvements in dyspnea and improved sleep. However, the severity of a patient's baseline dyspnea was not predictive of a response to the opiates. Whether the relief may persist during treatment longer than four days is not known. It should be noted that the Global Initiative for Chronic Obstructive Lung Disease (GOLD) does not recommend the use of low dose opiates in severe COPD.[37] Because of the potential risk for respiratory depression, the use of opiates for intractable dyspnea needs to be done on a case-by-case basis with due respect for potential side effects.

In summary, dyspnea is the distressing sensation that breathing is difficult, labored or unpleasant. The symptom is nonspecific because it is caused by many cardiopulmonary disorders. The evaluation of dyspnea in a patient begins by establishing whether the symptom is acute or chronic and this is followed by a detailed medical history and physical examination. Guided by history and physical examination findings, laboratory testing then is used to establish the underlying diagnosis. For this, chest radiographs, pulmonary function tests and Cardiopulmonary Exercise Testing (CPET) are frequently helpful. In general, treatment is aimed at the specific underlying diagnosis. However, nonspecific therapies aimed at the symptom rather than the diagnosis also play a supplementary role in the relief of dyspnea.

Wheeze and Respiratory Disease

J Mark Madison, Richard S Irwin

INTRODUCTION

Wheeze is either a symptom reported by a patient or a sign heard on the auscultation of the chest and neck during physical examination. Wheezes indicate airway obstruction somewhere in the respiratory tract and are defined as continuous musical sounds (approximately 100–1000 HZ) lasting more than 80–100 msec, but usually not more than 250 msec.[1-4] They can be inspiratory or expiratory, high or low pitched, consist of single or multiple musical tones and originate from any airway, either inside or outside of the thoracic cavity.[1-4] Stridor is a special type of wheeze and refers to inspiratory wheezing heard loudest over the central large airways of the chest and neck.

It is fundamental to understand that wheezing is a nonspecific finding that simply signifies the presence of airway obstruction, not its cause. It is not, by itself, diagnostic of any specific respiratory disease. Evaluation of the cause of wheezing begins with a medical history and physical examination and should be supplemented by diagnostic studies such as pulmonary function tests. In general, treatment of wheezing is specifically directed at the identified, underlying disease causing the airway obstruction, but nonspecific supportive therapy may be needed until definitive therapy is effective.

PHYSIOLOGY OF WHEEZE

Wheezes are caused by obstruction to airflow, but precisely how airway obstruction causes wheeze is not known.[5] Most likely, wheezes are caused by the oscillations or fluttering of airway walls and secretions in the airways. In accordance with the Bernoulli's principle describing the relationship between gas flow and pressure, air moving through an airway increases in velocity when it encounters a segment of airway that is narrowed. The higher gas velocity means lower airway pressure in that local region and, therefore, there is a tendency for the airway wall to collapse inward slightly. As the collapse increases, the worsening obstruction decreases airflow and increases pressure in the airway. Higher airway pressure in turn pushes the airway wall outward, partially relieving the obstruction and then the cycle starts again. This inward and outward movement of the airway wall happens cyclically to create an oscillatory vibration that is heard as a musical tone on the auscultation of the chest.

HISTORY AND PHYSICAL EXAMINATION

It is a common error to assume that the site(s) of airway obstruction can be reliably determined by physical examination. Determining the phase of the respiratory cycle (inspiratory vs expiratory) when wheezing is heard and noting the timbre of the wheezing (monophonic vs polyphonic) may be helpful clinically when combined with the other elements of patient evaluation, but these characteristics cannot, by themselves, be used to reliably identify the sites or causes of wheezing.

Inspiratory wheezing is neither a sensitive nor specific indicator of extrathoracic airway obstruction. It is true that extrathoracic obstruction of a large airway tends to produce inspiratory wheezing, because negative airway pressure during inspiration tends to augment the degree of narrowing as airway tissue collapses slightly inward.

However, inspiratory wheezing is an insensitive method of detecting extrathoracic obstruction since the lumen diameter must decrease to approximately 5 mm to produce stridor clinically.[6] Moreover, inspiratory wheezing is a nonspecific finding because inspiratory wheezing is frequently heard with expiratory wheezing due to intrathoracic obstruction in large or small airways such as obstruction due to asthma.[2,7] Moreover, wheezing due to asthma may sometimes be heard only on inspiration.

Expiratory wheezing by history or physical examination is neither sensitive nor specific for diagnosing asthma. Symptomatic asthma can present without wheezing and wheezing caused by other diseases can mimic the wheezing of asthma. In one clinical study, only 35% of patients referred to a pulmonary clinic for a history of difficult to diagnose wheezing ultimately proved to have asthma upon further evaluation.[8] Similarly, only 43% of patients with monophonic (see below) expiratory wheeze on physical examination proved to have asthma as the underlying cause of the wheeze.

The pitch of wheeze also does not indicate where, in the respiratory tract, the obstruction to airflow is located.[9] However, wheezing that sounds as though there are multiple different musical notes, so-called polyphonic wheezing, typically represents vibrations emanating from the large, central airways of the chest. In contrast, multiple wheezes of a single pitch (monophonic) typically reflect obstructions in the small, more peripheral, airways; however, monophonic wheezes can emanate from the vocal cords. Therefore, this distinction between monophonic and polyphonic wheezing is a general, not absolute, one and has not been studied clinically for its predictive and diagnostic accuracy.[2] Therefore, the timbre of wheezing may be helpful as additional clinical information, but should not be relied on exclusively for diagnostic decisions.

It should be emphasized that the loudness or amplitude of wheezing is not a reliable indicator of the severity of airway obstruction.[3,7,10,11] Because wheezing depends on airway narrowing and the amount of airflow, the amplitude of wheezing may be low even when there is severe obstruction present because there is very little airflow. For one classic example of this, it is an ominous finding when a patient with a severe exacerbation of asthma has a "silent chest" on physical examination.

PULMONARY FUNCTION TESTING

Spirometry and flow-volume loops can help a physician determine whether the airway obstruction causing wheeze is located in the extrathoracic upper airways, intrathoracic upper airways, or intrathoracic lower, small (< 2 mm diameter) airways.[2,3] These different regions of the airways have distinguishing physiologic characteristics that make pulmonary function testing informative when evaluating the cause of wheeze.[2,3,12,13]

Extrathoracic upper airway lesions can be located in the mouth, pharynx, larynx or extrathoracic trachea.[2,3,11,12] The word "variable" is used to describe an obstructed region of the airway that is pliable or deformable enough that the size of the lumen diameter is variable at the site of the obstruction depending on whether the patient is inspiring or expiring. Outside the thoracic cavity, the lumen diameter of the airway depends on the difference between lumen air pressure and atmospheric pressure. When a patient inspires, the airway lumen pressure becomes negative compared to atmospheric pressure and the pliable tissues of the airway collapse inward slightly (Fig. 21.1). When the patient expires, extrathoracic lumen air pressure is positive relative to atmospheric pressure and the airway wall is forced outward increasing the lumen diameter (Fig. 21.1). If there is a partially obstructing lesion narrowing the extrathoracic airway at a single point, this inward collapse during inspiration and outward movement during expiration can produce higher maximal air flows during expiration compared to inspiration. This physiology is best detected by performing flow volume loops during spirometric testing in the pulmonary function laboratory. In the presence of a variable extrathoracic lesion, inspiratory flows are limited and there is, therefore, a flow limitation or

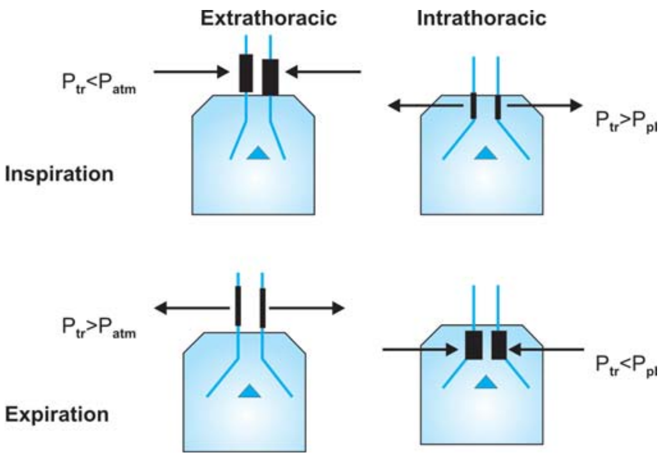

Fig. 21.1: Physiology of upper airway obstruction. Transmural pressure changes during inspiration and expiration affect the diameter of the airway lumen differently depending on whether the single site of obstruction is inside the chest cavity (intrathoracic) or outside the chest cavity (extrathoracic)

Volume

Fig. 21.2: Flow-volume loop configurations for airway obstruction. Flow-volume loops are useful for identifying the site of airway obstruction causing wheezing. For small, lower airways obstruction, there is a characteristic concave upward appearance on the expiratory limb of the flow-volume loop. For obstructions of the large upper airways, distinct patterns are evident for intrathoracic and extrathoracic sites of obstruction

“plateau” on the inspiratory limb of the flow-volume loop (Fig. 21.2). On the expiratory limb of the flow-volume curve, there is no corresponding flow limitation or plateau. When inspiratory and expiratory flow rates at 50% of vital capacity are compared, the ratio of the two is characteristically less than one. The patient having this pattern on the flow volume curve is said to have a variable extrathoracic upper airway obstruction.

A variable intrathoracic upper airway lesion has the opposite pattern on flow-volume loops because lumen diameter in intrathoracic airways is determined by the difference between lumen air pressure and pleural pressure.[2,3,12,13] During inspiration, pleural pressure is negative relative to lumen pressure and the pliable walls of the airways are pulled outward to increase lumen diameter (Fig. 21.1). During expiration, the opposite is true and the pliable airway walls collapse inward slightly (Fig. 21.1). If there is a partial narrowing of the airway at a single point, these differences in lumen diameter during inspiration and expiration can produce significant changes in airflow that, again, are best assessed on flow-volume loops. In the presence of a variable intrathoracic lesion, inspiratory flows may be unaffected by the presence of the lesion and so the inspiratory limb of the flow-volume loop appears normal or nearly normal. However, on expiration, when the airway diameter is smaller due to positive pleural pressure, there is a flow limitation or plateau on the expiratory limb of the flow-volume loop (Fig. 21.2). The patient having this pattern on the flow-volume loop is said to have a variable intrathoracic upper airway obstruction.

When the single obstructing lesion is “fixed” rather than variable, it means that the tissue at the site of the lesion is not pliable or deformable enough to allow significant changes in airway lumen diameter during inspiration and expiration. Therefore, the pattern on flow-volume loop is characteristically abnormal during both inspiration and expiration and there is a flow limitation or plateau on both limbs of the flow-volume loop (Fig. 21.2).

Unlike upper airway lesions, obstruction in the small intrathoracic airways is almost always at multiple scattered sites impeding airflow in a nonuniform manner. Diseases, such as asthma and Chronic Obstructive Pulmonary Disease (COPD) are among the most common causes of wheezing due to small airway obstruction. Spirometry is the main method of detecting and quantifying this airway obstruction.[14] The Forced Expired Volume in 1 Second (FEV_1) and the Forced Vital Capacity (FVC) are both reduced, but the FEV_1 is reduced out of proportion to the FVC such that the FEV_1/FVC ratio is abnormally low (less than the lower limit of predicted normal). For obstruction, an FEV_1 less than 50% of predicted, or less than 1 liter, indicates "severe" airway obstruction. The flow-volume loop of a patient with obstruction of the lower airways characteristically shows a concave upward appearance on the expiratory limb of the flow-volume loop (Fig. 21.2). Spirometry repeated after the inhalation of drugs or medications or after a treatment course can also be helpful in evaluating the causes of airway obstruction.[2,3] For example, in the presence of airway obstruction, spirometry repeated after the administration of bronchodilator or after a course of corticosteroids may reveal the presence of reversible airway obstruction consistent with a diagnosis of asthma. For another example, in the absence of airway obstruction at baseline, a nonspecific bronchoprovocation challenge test (e.g. methacholine inhalation challenge test) may reveal the presence of bronchial hyperresponsiveness consistent with a diagnosis of asthma.

It is sometimes possible to detect coexisting small and large airway obstructions by taking advantage of the fact that helium is less dense than air. Airflow in small airways, having mainly laminar flow, is unaffected by substituting less dense helium for the nitrogen in air.[2,3,15] However, in large airways, where there is much turbulent gas flow, breathing a helium-rich gas mixture allows higher rates of gas flow compared to breathing air. Therefore, if a comparison of maximal expiratory flows for breathing air versus heliox (20% oxygen/80% helium) shows significantly greater gas flow with the helium mixtures, the patient is likely to have an obstructing lesion in a large airway with turbulent gas flow as part of his/her problem.

DIFFERENTIAL DIAGNOSIS FOR WHEEZING

Because the causes of airway obstruction are multiple, it is not surprising that wheezing appreciated by history or physical examination is a nonspecific finding.[8] Any cause of airway narrowing can result in wheezing and these causes include dynamic collapse of the airways; bronchospasm; airway wall edema, thickening or inflammation; airway secretions; remodeling of the airways; distortions of airway anatomy; and any compressing or partially obstructing mass (Table 21.1). It is a common error of physicians to mistakenly assume that all wheezing is due to asthma and this pitfall in evaluation should be avoided.

TABLE 21.1: Causes of wheeze*

*Table adapted from Reference 3. See Reference 3 for more detailed and referenced list. UARS is upper airway cough syndrome

One clinical study examined the spectrum and frequency of the causes of wheezing among patients referred to a pulmonary clinic for evaluation[8] (Fig. 21.3). Thirty-four patients with wheezing of unclear etiology were referred to an ambulatory pulmonary clinic for further evaluation that included methacholine inhalation challenge testing. Interestingly, only 35% of these patients had methacholine challenge tests that were consistent with asthma being the underlying cause of their wheezing. The most common cause of wheeze among these patients was not asthma, but, instead, postnasal drip syndrome (46% of cases).[16] Postnasal drip syndrome (now referred to as upper airway cough syndrome or

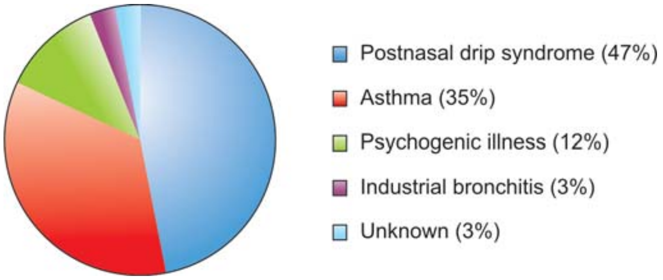

Fig. 21.3: Spectrum and frequency of the causes of wheezes. Adapted from reference 8. In this study, patients referred to a pulmonary clinic for difficult to diagnose wheezing were evaluated. Postnasal drip syndrome (now referred to as UACS) was the most common cause of difficult to diagnose wheezing among these patients. Vocal cord dysfunction syndrome is an example of a potential psychiatric illness presenting as wheeze

UACS) is a common condition and known to cause upper airway obstruction so it is not surprising that it can commonly result in wheezing.

Assessing the acuity of wheezing and the patient's overall clinical condition is an important part of the clinical evaluation and this is helpful in narrowing diagnostic possibilities, assessing the urgency of the clinical situation and planning management. For acute onset wheezing, the physician must assess the overall clinical presentation and judge whether there is a life-threatening cause of the wheezing. If so, the physician must rapidly institute specific therapy directed at the underlying disease process and support the patient until that specific therapy has had time to be effective. Obviously, not all acute or recent onset wheezing represents an urgent medical condition and that is why clinical judgment is used to assess the overall clinical presentation. It is beyond the scope of this chapter to comprehensively review the diagnosis and management of the many different diseases that cause wheezing (Table 21.1). Instead, selected diseases will be emphasized and categorized anatomically as either upper or lower airway conditions.

Upper Airway Conditions

UACS is a common cause of upper airway obstruction and therefore a common cause of wheezing.[8] The condition may be either acute or chronic and is caused by many rhinosinus diseases.[16] Acute presentations are most commonly due to the common cold. Chronic presentations can be due to allergic, perennial, non-allergic, postinfectious, environmental irritant, and vasomotor rhinitis and/or sinusitis. Consider the diagnosis when a patient describes the sensation of secretions or dripping in their throat, the frequent need to clear their throat, or frequent nasal discharge, or if patients are heard to frequently clear their throats even when they are not aware of doing it. Mucoid or mucopurulent secretions in the oropharynx or a cobblestone appearance of the pharyngeal mucosa suggest the diagnosis on physical examination.

Epiglottitis (supraglottitis) is an acute, potentially life-threatening, infection of the supraglottic region of the upper airway.[17] The infection can be caused by bacteria, viruses, or fungi, but *Haemophilus influenzae* is the most common cause. In adults, consider the diagnosis if the complaint of acute or recent onset throat pain is severe and out of proportion to the inflammation seen on physical examination of the posterior oropharynx, especially if there is respiratory distress, fever, drooling, and changed voice. Lateral neck radiographs and computed tomography of the neck can be helpful in further clinical evaluation.

Vocal cord dysfunction syndrome can cause wheeze or stridor because the upper airway is obstructed by the paradoxical adduction of the vocal cords during inspiration.[18,19] The syndrome is thought to be frequently due to emotional distress or trauma and may be difficult to diagnose when the symptoms are intermittent. It can be difficult to distinguish from asthma and, in fact, sometimes coexists with asthma.[18] An arterial blood gas may be helpful in distinguishing wheezing due to vocal cord dysfunction from that due to small airway obstruction because the alveolar-arterial oxygen tension difference would be expected to be high in asthma, but not in upper airway obstruction. Early and abrupt decreases in flow rates during inspiration on flow-volume loop can suggest the diagnosis, but usually the diagnosis is confirmed endoscopically by observing the movement of the unanesthetized vocal cords during inspiration. While initially thought to be provoked by psychogenic factors, the syndrome has also been reported in elite athletes during vigorous exercise and associated with UACS and Gastroesophageal Reflux Disease (GERD).

Laryngotracheal injury caused by endotracheal intubation is another potential cause of upper airway obstruction and, therefore, wheezing.[20] The injury can occur during the process of intubation or as a result of an endotracheal tube being in the airway for a prolonged period of time. The tissue injury can lead to obstruction in the supraglottic regions of the upper airway, at the vocal cords, or in the trachea itself. Obstructing tracheal lesions can be due to edema and/or granulation or fibrous tissues that form at the site or near the tip of the endotracheal tube. The condition is often easily missed in patients who were recently intubated for respiratory failure due to asthma or COPD. For example, in follow-up, persistent or poorly resolving respiratory symptoms can be mistakenly ascribed to the patient's underlying asthma or COPD and wheezing due to upper airway obstruction may be missed. The diagnosis should be suspected in any patient who has unexplained or persistent respiratory symptoms, especially wheezing or stridor, following endotracheal intubation. Flow-volume loops and direct endoscopic visualization of the upper airway are frequently helpful in further evaluation; comparing maximal expiratory flows during air and helium/air mixtures may uncover the large airway obstructing component as described above (see section on Pulmonary Function Testing).

Lower Airway Conditions

Asthma obstructs large and small intrathoracic airways due to bronchospasm, secretions, and inflammatory infiltration and edema of the airway walls.[21] Asthma is characterized by partially or fully reversible airway obstruction and bronchial hyperresponsiveness. Wheezing in patients with asthma may be chronic or absent during the periods of remission. It is important to again emphasize that although asthma is strongly associated with wheezing, not all patients with asthma wheeze. Patients suspected of having asthma should be evaluated with pulmonary function testing. If there is airway obstruction evident on baseline testing, then a 12% increase in FEV_1 or FVC upon the inhalation of bronchodilator (e.g. a short and rapidly acting beta-adrenergic agonist) suggests reversible airway obstruction. If there is no airway obstruction present at baseline, then nonspecific bronchoprovocation testing (e.g. methacholine inhalation challenge) is helpful in establishing the presence of bronchial hyper-responsiveness.[21] Because a positive methacholine challenge test, alone, is not diagnostic of asthma, improvement in asthma symptoms must be observed during specific treatment for asthma in order to establish the diagnosis.

COPD is a disease process consisting of varying degrees of emphysema and chronic bronchitis that leads to chronic airway obstruction.[22] Although COPD can be caused by hereditary diseases (e.g. alpha-1-antitrypsin deficiency), air pollutants from the burning of biomass fuels, and exposure to smoke from cook fires, the most common cause of COPD worldwide is tobacco smoking.[22,23] Whether tobacco is consumed by smoking cigarettes, cigars, pipes, beedi (bidi), hookahs, kreteks, or even the passive inhalation of tobacco smoke, the toxic products of tobacco combustion clearly and widely recognized to be linked to the development of COPD (chronic bronchitis and emphysema) and worldwide. The history or physical finding of wheezing in a moderate to heavy smoker should raise the possibility of COPD and prompt further evaluation for chronic airflow obstruction by pulmonary function testing. Although exceptions are frequently observed, patients with COPD typically have no, or only very small responses to inhaled bronchodilators on pulmonary function testing. However, it is important to consider that, because both COPD and asthma are common, these diseases may coexist in an individual patient.

Pulmonary edema due to congestive heart failure is a well-recognized cause of airway obstruction and wheezing—so called cardiac asthma.[24] Most likely, the airway obstruction is due to airway wall edema and peribronchial edema that narrows the caliber of the lower airways. However, some evidence suggests that bronchial hyperresponsiveness may also play a role in the airway obstruction.[3] Theoretically, any cause of pulmonary edema, whether cardiac or noncardiac, could lead to airway wall edema, airway obstruction and wheezing. When congestive heart failure is suspected as a cause of wheezing, measurement of serum B-Type Natriuretic Peptide (BNP) levels and/or echocardiography may be helpful in further evaluation.

Aspiration of secretions into the airways is common and can lead to respiratory symptoms, including wheezing, especially when the frequency and/or volume of aspiration is high.[25] The wheezing may be due to laryngeal irritation, tracheobronchitis, obstruction of airways from aspirated material, or peribronchial edema. Aspiration as a cause of wheezing should be suspected when there are predisposing factors associated with aspiration and when wheezing is associated with diffuse or multiple focal infiltrates on chest radiograph, especially in a posterior or inferior location. Predisposing factors the clinician should look for include hiatal hernia, Zenker's diverticulum, esophageal dysmotility, nasogastric feeding tubes, GERD, medications that lower esophageal sphincter pressure (e.g. calcium channel antagonists), pharyngeal dysfunction (e.g. strokes, amyotrophic lateral sclerosis), sedative use, alcohol abuse, and advanced age.[3] Diagnostic tests that can be helpful to further evaluate for aspiration include bedside swallowing evaluation, modified barium swallow, and 24 hour esophageal pH and impedance monitoring to assess for GERD.

Acute Venous Thromboembolism (VTE) may result in wheezing and can be confused clinically with the presentation of acute asthma.[26] The wheezing may be due to bronchoconstriction of small airways responding to platelet-derived mediators such as thromboxanes, serotonin and histamine. Typically, bronchospasm due to VTE is poorly responsive to bronchodilators.[26] Because the treatment for VTE is immediate systemic anticoagulation, it is important to at least consider the possibility of VTE in any patient presenting with acute wheezing, especially if there are risk factors for deep venous thrombosis.

Anaphylaxis is a systemic allergic reaction that may obstruct the upper (e.g. laryngeal edema) and lower airways (bronchoconstriction, mucosal edema, airway secretions) to produce wheezing.[27] It is typically of abrupt onset and may feature dyspnea, wheezing, urticaria, angioedema, nausea, abdominal pain, diarrhea and hypotension. It may be due to an acute allergic sensitivity to any agent, but is often due to an allergy against drugs or medications and stinging insects or due to a sensitivity to contrast agents.

Parasitic infections may also cause wheezing. Wheezing has been reported with infections due to species of *Strongyloides, Ascaris, Ancylostoma, Necator, Echinococcus, Toxocara, Schistosoma, Brugia, Dirofilaria*, and filarial species.[3] With an incubation period of 1–2 weeks depending on the species of parasite, Löffler's syndrome is seen in parasitic infections that feature the migration of parasite larva through the lungs during an acute infection. It is recognized clinically as fever, urticaria, wheeze, cough and rarely hemoptysis.[28] Laboratory findings include eosinophilia and migratory and transient infiltrates on chest radiograph. Parasites should be suspected as a cause of wheezing when there is wheeze in a patient without a history of asthma or COPD, when there has been travel or residence in an endemic area, fatigue, weight loss, fever, and infiltrates on chest radiograph.

APPROACH TO THE DIAGNOSIS OF WHEEZE

An approach to the diagnosis of wheezing uses a combination of history, physical examination and pulmonary function testing (Table 21.2). First, identify any associated symptoms or signs that might suggest specific diagnoses. Second, assess whether the wheezing is potentially life-threatening and either acute or chronic, recognize the spectrum and frequency of the causes of wheeze, and then narrow the differential diagnosis by localizing the site of the wheezing to the intrathoracic versus extrathoracic airways.

TABLE 21.2: Diagnostic tests useful in the evaluation of wheeze

Pulmonary function tests
- Spirometry
- Flow-volume loops
- Bronchodilator testing
- Nonspecific bronchial provocation testing
- Spirometry comparing air and oxygen-helium mixtures

Imaging
- Chest radiograph
- Sinus radiographs for assessing sinusitis causing UACS
- Lateral neck radiograph for assessing upper airway obstruction
- Computed Tomography (CT) of the chest, neck or sinuses
- CT angiography for assessing venous thromboembolism
- Echocardiography and other imaging for assessing cardiac function

Endoscopy
- Laryngoscopy
- Bronchoscopy

Evaluation for aspiration
- Bedside swallowing observation
- Modified barium swallow
- 24-hour esophageal pH and impedance monitoring

Blood tests
- Complete blood count and differential to assess for eosinophilia
- B-Type Natriuretic Peptide (BNP)
- D-dimer

Evaluation for parasites
- Stool for ova and parasites
- Microscopic examination of sputum and gastric washings for larva
- Serologic testing for parasites (e.g. schistosoma, strongyloides, filaria)

TREATMENT

Because the causes of wheezes are many, it is beyond the scope of this chapter to review the treatment of all the various diseases and disorders that can cause wheezing. In general, however, treatment of upper or lower airway obstructions should be specific and directed at the underlying disease.

In treating the severely obstructed patient with impending respiratory failure, supportive measures may be needed until specific therapy has had time to be effective. Supplemental oxygen should be administered and the patient's respiratory status monitored closely by clinical examination and oxygen saturation. Oral endotracheal intubation or tracheostomy may be needed to bypass critical obstruction of an upper airway and/or to support gas exchange and increased work of breathing caused by severe upper or lower airway obstructions.

For severe obstructions of the upper airway, helium and oxygen gas mixtures (40% or 80% helium and 60% or 20% oxygen, respectively) can be helpful in supporting the patient as a bridge to more definitive therapy.[29] The density of helium is low and therefore it lowers the resistance and the work of breathing when airflow is turbulent (as in the upper airways) rather than laminar (as in the lower, smaller airways).[30] In contrast, for asthma and COPD, disease processes that obstruct the small intrathoracic airways where air flow is mainly laminar, helium-oxygen mixtures may have a role, but their routine use is controversial and not currently recommended in treatment guidelines.[21,22,31]

In summary, wheezing indicates obstruction to airflow in the lower and/or upper airways. It is important for physicians to recognize that not all wheezing is due to asthma and not all asthma produces wheezes. A broad range of cardiopulmonary diseases and a variety of different infections can cause wheezing, whether the onset and timing be acute or chronic. Evaluation for the underlying cause of wheeze in a given patient, starts with a thorough history and physical examination and can be aided by additional laboratory and radiographic studies, especially pulmonary function testing. In general, treatment of wheezing should be specifically aimed at the identified underlying diagnosis. However, in the acute setting, mixtures of helium and oxygen may provide rapid, temporary relief for severe upper airway obstructions.

History and Physical Examination

PR Gupta

INTRODUCTION

In spite of rapid advances in diagnostic tools and their wide spread availability, clinical history and physical examination continue to play an important role in assessing the medical illness of a patient. Respiratory illnesses are no exception. Optimal time required for history taking, physical examination, formulation of differential diagnosis, decision making and writing the treatment/instructions to the patients is about an hour, but in a crowded outpatient department as in India, this is usually accomplished in 5 to 10 minutes. Hence, it is necessary for every physician to acquire the necessary skills to obtain all important information in the given time to arrive at the clinical diagnosis, without missing the important points. Many a time, quick decisions regarding treatment are required on the basis of clinical evaluation alone. It is true to a great extent that the clinicians are natural bayesians and their reasoning about patients is intuitive, probabilistic, and reiterative.[1] Such subjective, context dependent reasoning is integral to clinical judgment, especially useful when diagnosing rare diseases.

HISTORY TAKING

The guiding principle to history taking is: "Listen to the patient as if he is revealing the diagnosis". Allow the patient to speak about his illness in his own words. Avoid unnecessary interruptions except when it becomes essential to seek details on certain issues. Selective open-ended questions may be asked, but avoid leading questions. Some patients describe their illness aimlessly with irrelevant details. It should be gently curtailed. When a patient is too ill to give a coherent account of his illness, history should be taken from a relative or an attendant. Begin with history of the presenting symptom. Details of time scale of each symptom is essential, whether it is progressive or static, constant or paroxysmal. Ask for aggravating or relieving factors, if any. In respiratory system, common symptoms include cough, chest pain, hemoptysis, shortness of breathing and/or wheezing. Each of the symptoms has been discussed in detail in the respective chapters.

Cough

Cough is a reflexive or deliberate explosive expiratory act. It is a physiological act, meant to clear the airways, but when it becomes troublesome, it prompts a visit to physician. Psychogenic stress may cause or aggravate cough due to organic causes.[2] Chronic maxillary sinusitis, asthma, postviral reactive airway disease syndrome and inhaled foreign bodies commonly cause persistent cough during childhood. In nonsmoker adults, asthma, postnasal drip, reactive airway disease syndrome and gastroesophageal reflux predominate, but in the elderly, asthma, cardiac failure and gastroesophageal reflux are the more common causes of cough (all may lead to nocturnal cough). Use of an angiotensin-converting enzyme inhibitor[3] causing dry cough should always be kept in mind. Smokers usually do not complain of cough, but when it is associated with excessive sputum, blood or dyspnea, it may point to an underlying disease, i.e. Chronic Obstructive Pulmonary Disease (COPD) or bronchogenic carcinoma.

History should cover the duration and characteristics of cough, whether dry or productive of sputum or blood, provocative factors, such as cold, smoke, change of posture or eating, and accompanying symptoms to find out the likely causes, i.e. running nose and sore throat (postnasal drip); fever; chills and pleuritic pain chest (pneumonia); heartburn (gastroesophageal reflux); weight loss and night sweats (chronic infection or tumor); choking sensation and difficulty in swallowing while eating or drinking (aspiration).[4]

Sputum

A patient having productive cough should be asked regarding the time course, amount, character, viscosity, taste and color of the sputum. Early morning sputum in smokers suggest chronic bronchitis, but if it occurs while going to bed, it suggests bronchiectasis or lung abscess. Most children and adult females usually do not spit and swallow their sputum, but its presence should be assessed by the sound of their cough. It is usually not possible to measure the exact amount of sputum, but can be assessed from the number of spits, spoonfuls or cupfuls. Sputum may be very foul smelling in lung abscess or bronchiectasis.

It is better to inspect the sample of sputum as the patient may not be able to describe its exact character, viscosity and color. Sputum may be serous (pulmonary edema, bronchioalveolar carcinoma), mucoid (chronic bronchitis/COPD, asthma) or mucopurulent/purulent (bronchiectasis, lung abscess, pneumonia). Viscous sputum is often difficult to expectorate (asthma). In anaerobic infections, sputum is foul in taste and smell. Sputum is yellow, green or brown in bronchopulmonary infections, green if it contains eosinophils, golden yellow or green in bronchobiliary fistula, rusty in pneumococcal infections, red currant jelly type in *Klebsiella pneumonia*, anchovy sauce colored in ruptured amoebic liver abscess, and black in coal workers pneumoconiosis. Sputum may contain brown or black casts in recovery phase of asthma or Allergic Bronchopulmonary Aspergillosis (ABPA).[5]

Hemoptysis

Hemoptysis is coughing out blood from respiratory tract, mainly the lungs. Mild hemoptysis, often seen as blood streaking, is a common symptom. Lungs have been provided with a dual blood supply namely the low-pressure pulmonary arteries (95%) and the high-pressure bronchial (systemic) arteries (5%). Hemoptysis mostly originates from the later except in the cases of trauma or erosion of pulmonary arteries or inflammation of pulmonary capillaries. Efforts should be made to differentiate true hemoptysis from hematemesis, epistaxis or bleeding from oral cavity by asking the patient about the temporal patterns.[6] Hematemesis generally follows nausea, vomiting or retching; in epistaxis, the patient feels sensation of postnasal drip or bleeding from nares without coughing, but hemoptysis follows coughing. The type of blood can also help to detect the source (bright red often mixed with frothy sputum in hemoptysis versus the dark black, often in clumps and mixed with food, in hematemesis).[6]

History should cover its onset (sudden, recurrent or cyclical), duration, provoking factors (exertion, change of position, exposure to cold, smoke or allergens) and amount (streaking or massive). Hemoptysis is seldom a solitary event. Associated symptoms may provide clue to the cause of hemoptysis, i.e. chest pain (pulmonary embolism), dependent edema, orthopnea and paroxysmal nocturnal dyspnea, fever and cough (pneumonia), weight loss (TB or cancer), bloody nasal discharge (Wegener's granulomatosis), hematuria (Goodpasture's syndrome, Wegener's granulomatosis), and bleeding from other sites or easy bruising (coagulopathy). Enquire about the risk factors as it may provide the likely etiology, i.e. Human Immunodeficiency Virus (HIV) infection or use of immune-suppressant drugs (TB and fungal infections), long-standing smoking history (lung cancer) or a recent history of immobilization, travel for long distances, surgery, pregnancy, cancer or use of oral contraceptives (pulmonary thromboembolism).

Chest Pain

Chest pain is a common complaint, but patient's perception may vary. To some, it is a warning of potential life-threatening illness, they may seek repeated consultations even when the symptom is trivial. Others, including those with serious illnesses, may tend to ignore. However, a physician should never discard the symptom without exploring its etiology. Chest pain may have its origin from disorders of chest wall, pleura, lungs, heart/great vessels, esophagus and subdiaphragmatic structures (Table 22.1).

History of chest pain should include its duration, location (including radiation to other areas, if any) and character, i.e. heaviness, tearing, burning, stabbing, sharp needle like, urge to eructate or merely a discomfort. Precipitating factors, such as physical or psychological stress, respiratory efforts, coughing or swallowing, and relieving factors (such as leaning forward) should be enquired. Associated symptoms like cough, dyspnea,

TABLE 22.1: Common causes of chest pain

	Causes	*Likely character of chest pain*
Pulmonary	Tumors	Mostly dull aching in character
	Pneumonia	Often pleural in character
	Pulmonary embolism/infarction	Central, sharp and sinking in character
Pleural	Pneumothorax	Sharp, stabbing in character, worse on coughing
	Hemothorax	
	Effusion/empyema	
	Pleuritis	
	Tumors	
Cardiovascular	Myocardial ischemia/infarct	Central, sharp and sinking in character, radiating to left arm
	Myocarditis	Mostly dull aching in character
	Pericarditis	Sharp, stabbing in character
	Dressler's syndrome	Sharp, stabbing in character or dull aching
	Dissecting aortic aneurism	Sharp, tearing in character
	Mitral valve prolapsed	Mostly dull aching in character
Esophageal	Spasm	Central lower chest and sharp in character
	Rupture	
	Esophagitis/ulceration	
	Neoplasm	Mostly dull aching in character
	Achlasia	Burning in character
	Diverticula	
	FB	Sharp, stabbing in character
Gastrointestinal	Liver abscess	Sharp and throbbing in character
	Pancreatitis	Sharp, stabbing, radiating to back
	Whipple's disease	Mostly dull aching in character
Chest wall	Skin lesions/herpes zoster	Sharp and sometimes throbbing in character
	Breast lesions	Mostly dull aching in character
	Musculoskeletal lesions	Often with cough, dyspnea and fever
	Infection/tumor in spine/rib	Localized and sharp
	Trauma	Often pleural in character, local tenderness
Mediastinal	Tumors	Mostly dull aching in character
	Inflammation	Central and sharp in character
Referred pain	Abnormalities of subdiaphragmatic structures	Boring in character, no local tenderness
Miscellaneous	Subdiaphragmatic abscess	Sharp and throbbing in character
	Psychoneurosis	Always severe, worse in presence of attendants

palpitation, syncope, diaphoresis, nausea, vomiting, fever and chills, weakness, malaise and weight loss should be asked for. Leg pain and swelling may point to deep vein thrombosis and pulmonary thromboembolism.

Dyspnea

Dyspnea is an unpleasant or uncomfortable awareness of breathing. In most situations, it occurs due to an imbalance between neurological stimulation and the mechanical changes that occurs in the lungs and the chest wall, the resulting mismatch of ventilation and its demand.[7] A variety of scaling methods have been used to quantify dyspnea, i.e. Borg Category Scale, Visual Analogue Scale and American Thoracic Society Scale, but none can be universally applied to all the patients.[8] For epidemiological purposes, the one suggested by the Medical Research Council is quite useful.[9]

A host of pulmonary, cardiac or other disorders may lead to dyspnea. History should cover its duration, onset (sudden or insidious), severity and exacerbating or relieving factors like exertion or rest, supine or sitting position and exposure to cold, dust, smoke or allergens. Associated symptoms may provide useful clue to the cause of dyspnea, i.e. chest pain (pulmonary embolism, myocardial infarction), dependent edema, orthopnea or paroxysmal nocturnal dyspnea (cardiac failure), wheezing (asthma), fever or cough (pneumonia), black stools or heavy menses (anemia) and weight loss (TB or cancer). A patient with psychogenic dyspnea is symptomatic more often during rest than on exertion.

Upper Respiratory Tract Symptoms

A brief history of upper respiratory tract symptoms, more particularly running of nose, itching, sneezing, congestion, discharge of blood or blood mixed secretions or blocked nose, should always be obtained while assessing a patient for respiratory illness. These symptoms may point to specific respiratory (asthma) or systemic illnesses (sarcoidosis, Wegener's granulomatosis, etc.).

General Symptoms

Once the assessment of the respiratory symptoms is over, the patient should be asked for the presence of general symptoms and those pertaining to other systems. Presence of fever, loss of appetite, weight loss or anemia signifies serious illness. History of associated urinary symptoms, dysphasia, joint pain and skin lesions may point to an important systemic illness. Symptoms pertaining to cardiac and neuromuscular diseases may unravel the cause of respiratory illness, particularly of dyspnea.

HISTORY OF PREVIOUS DIAGNOSIS AND TREATMENT

Most patients visit a pulmonologist only after consulting their family physician. It is always worthwhile to ask the patient about the details of such consultations, investigations already done, diagnosis made, treatment offered and the outcome thereof. Often, a correct diagnosis is missed for want of time and skill, but even if a diagnosis is made, the treatment may be wanting in the terms of drugs, dosages and compliance. Past history of incorrect or irregular treatment of tuberculosis (TB) may have resulted in drug failure (and drug resistance), relapse, bronchiectasis, aspergilloma or chronic necrotizing pulmonary aspergillosis.[10] Drugs taken for other illnesses may be responsible for the current illness, e.g. busulphan causing pulmonary fibrosis, ACE inhibitors causing cough, aspirin and Nonsteroidal Anti-inflammatory Drugs (NSAIDs) causing asthma, and so on.

Past Medical History

Past medical history of the patient, many a times, gives an important clue to the etiology of the current illness. Ask about childhood illnesses like fever, cough and cold, more so, if it is recurrent, as these may end up in asthma, COPD or bronchiectasis during adult life. History of wheezy bronchitis in childhood may unravel the diagnosis of asthma in adults. Chest injuries in past (particularly those with hemothorax) may end up in frozen chest. History of recurrent loss of consciousness in the past may point to lung abscess. Surgery or pregnancy in recent past suggests pulmonary thromboembolism. Indeed, history of infections, trauma, surgery, malignancies or prolonged bed rest in past, all may provide important clue to the diagnosis of the current illness.

Important lifestyle diseases that may have impact on respiratory system include diabetes mellitus and obesity. Also assess for allergy to food, drugs and/or dust, as this may give an important clue to the diagnosis of rhinitis/asthma. At times, comparison of the recent chest radiograph with the old may provide great diagnostic value.

Personal History

Patient's lifestyle and personal habits like smoking or alcohol consumption, along with the details of the quantum, frequency and its duration, are integral parts of a good history-taking. Exposure to pets and animals may be responsible for serious or recurrent respiratory illness. Present or past occupational exposure to organic dust like bagasse or hay or inorganic dust like silica, coal or asbestos may some times help to unravel the diagnosis in most difficult situations. History of extramarital or promiscuous sexual practices may point to the coexisting HIV and acquired immunodeficiency syndrome (AIDS) or other infections.

THE PHYSICAL EXAMINATION

After the history-taking, the clinician has already some idea regarding the likely diagnosis and what to expect of the physical examination. However, a systematic approach to physical examination is always rewarding and may obviate the need of unnecessary investigations at a later stage. This includes a general physical and respiratory system examination as well as a quick review of other systems. For details regarding the methods of examination, the reader is referred to various books on clinical methods in medicine.[11-13]

General Physical Examination

Always begin by examining the general appearance of the patient, breathing pattern and the recording of vital signs, such as the rate, rhythm and character of pulse and respiration, blood pressure and temperature. An anxious look indicates acute illness while the presence of fatigue and cachexia point to a chronic disease or malignancy. A plethoric appearance may be seen in polycythemia, most commonly as a result of chronic lung disease or Superior Vena Cava (SVC) obstruction (Fig. 22.1). Look at the tongue, soft palate and the nail beds for cyanosis, anemia or polycythemia, at fingers for clubbing, at face, neck, hands and feet for edema; and at neck for any lymphadenopathy or abnormal pulsations/fullness of veins. Look for nicotine stains on the intertriginous surfaces of the second and third fingers (in cigarette or *bidi* smokers) or the palm (in *chillum* or *hookah* smokers). Note down wheeze, stridor or voice abnormality, if any.

Breathing Pattern

Breathing pattern should be observed throughout the clinical examination. Normal breathing is quiet with a frequency of between 12 and 18 per minute. An increased respiratory rate (tachypnea) is seen in the presence of anxiety, anemia, asthma, restrictive lung diseases, pulmonary artery hypertension and hypoxia of any etiology. A slow respiratory rate (bradypnea) may be attributed to decreased respiratory drive as a result of drug overdose or lesions of the central nervous system. Use of the accessory muscles of respiration or pursed lip breathing, which indicate severe illness, should be recorded. Noisy breathing indicates the narrowing of central airways, such as from carcinomatous lesions of vocal cord or trachea, or intrinsic lesions of vocal cords like palsies. When such obstruction is severe, the sound assumes a musical note on inspiration, occasionally during expiration also. This is called as croup or stridor. Wheezy breath sound, audible to unaided ears, are produced by the narrowing of intrathoracic airways, e.g. in asthma. Periodic breathing patterns, including Cheyne-Stokes and Biot's breathing, are usually associated with left heart failure and disorders of the central nervous system. In Kussmaul breathing, the depth of respiration is increased more than the rate. This pattern most often occurs in severe metabolic acidosis, but may be seen in an anxious person. The resultant hyperventilation in the latter may lead to respiratory alkalosis, weakness, dizziness and muscle cramps (tetany).

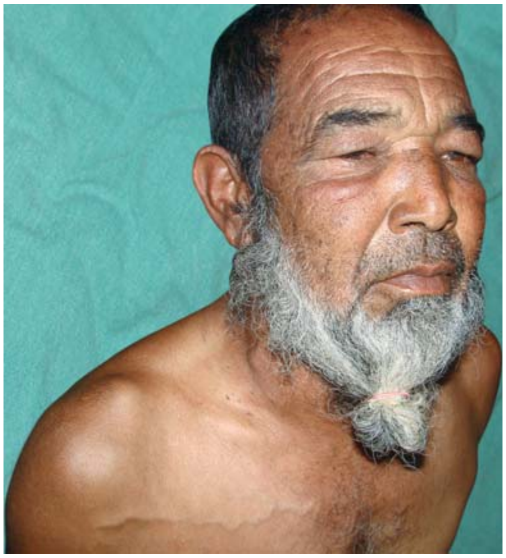

Fig. 22.1: Plethoric appearance of face in a patient with superior vena cava obstruction

Cyanosis

Cyanosis is the bluish discoloration of the tongue and the soft palate (central, when it mostly reflects arterial hypoxemia) or of nail beds and lips (peripheral, when it may reflect arterial hypoxemia due to low blood flow). Methemoglobinemia or sulfhemoglobinemia also causes bluish discoloration of the tongue and the soft palate, the nail beds or the lips. Severe chronic hypoxemia, pulmonary or cardiac, responsible for central cyanosis (Table 22.2) is often associated with polycythemia.

TABLE 22.2: Common causes of cyanosis

Pulmonary	*Cardiac*	*Others*
Pneumonia	Pulmonary edema	Central apneas
Atelectasis	Congenital heart disease	High altitude
Asthma/COPD	Pulmonary thromboembolism	
Interstitial lung diseases	Decreased cardiac output	
Pulmonary AV fistulas		

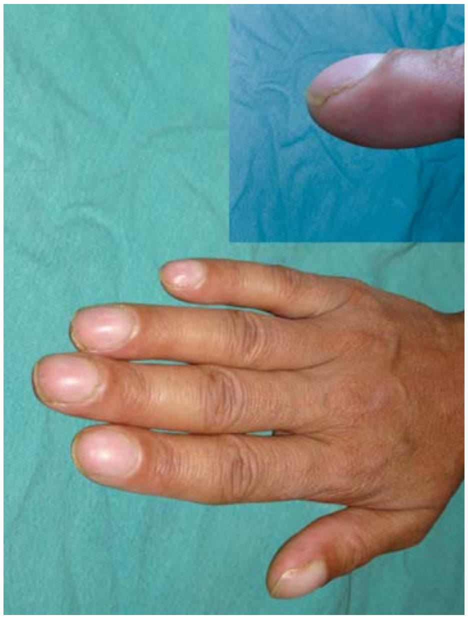

Fig. 22.2: Clubbed fingers. Insert showing the same in side profile. Note the convexity of nail and the loss of the normal angle between the base of the nail and the adjacent dorsal surface of the finger

Peripheral cyanosis (often with edema) affecting face, neck (and sometimes the upper limbs) may indicate SVC obstruction, and that of lower limbs, the inferior vena cava obstruction. In carbon monoxide poisoning, the organs are discolored as cherry red.

Clubbing

Clubbing is characterized by the diffuse bulbous enlargement of the terminal phalanges (Fig. 22.2). Early changes consist of thickening of the fibroelastic tissue of the nail bed, which can be detected by the loss of the normal angle between the base of the nail and the adjacent dorsal surface of the finger. This finding is demonstrated best when the finger is viewed from the side. Finger clubbing can occur in various pulmonary, cardiac and abdominal diseases (Table 22.3). Rarely clubbing may be congenital (familial) in origin. With time, it may progress to Hypertrophic Pulmonary Osteoarthropathy (HPOA). At this stage, the patient may complain of bone or joint pains.

Lymphadenopathy

Lymphadenopathy is abnormal enlargement of lymph glands (> 0.5 in size) at neck, axilla, groin and other external or internal sites. Note down the number, size, consistency and fixity of the lymph nodes to each other, the underlying tissues or to the overlying skin. Large fixed masses indicate metastasis, while firm and matted nodes may point to tuberculosis. Lymph nodes in Hodgkin's lymphoma are classically described as large, soft and rubbery in character.

Miscellaneous Physical Findings

Upper respiratory tract (nasal cavity, nasopharynx, nasal sinuses, oropharynx and the larynx) needs to be examined sequentially, this may help clinch the diagnosis, e.g. discharging nasal lesion in Wegener's granulomatosis. Thyroid gland should also be examined to detect abnormality in its shape, size and consistency. Other lesions that may provide clue to the underlying respiratory pathology include skin lesions, such as erythema nodosum in sarcoidosis and TB (Fig. 22.3), malar rash in systemic lupus erythematosus, dermatomyositis, subcutaneous nodules in metastatic carcinoma, eye lesions (phlyctenular conjunctivitis) in TB (Fig. 22.4), Horner's syndrome in lung cancer, iridocyclitis in TB and sarcoidosis, chemosis in SVC obstruction, hypercapnia and flapping tremors in type II respiratory failure.

Examination of the Chest

Examination of the chest is traditionally done with the help of inspection, palpation, percussion and auscultation in that order, but some physicians combine inspection with palpation. It is best done in the sitting posture with arms at the side.

Inspection

Appearance, shape and size of chest: Normal chest is bilaterally symmetrical and elliptical in cross-section.

TABLE 22.3: Common causes of clubbing

Pulmonary	*Cardiac*	*Enteric*
Tumors of lung	Congenital heart disease	Cirrhosis liver
Mesotheliomas	Bacterial endocarditis	Ulcerative colitis
Suppurative lung diseases		Coeliac disease
Idiopathic pulmonary fibrosis		Crohn's disease

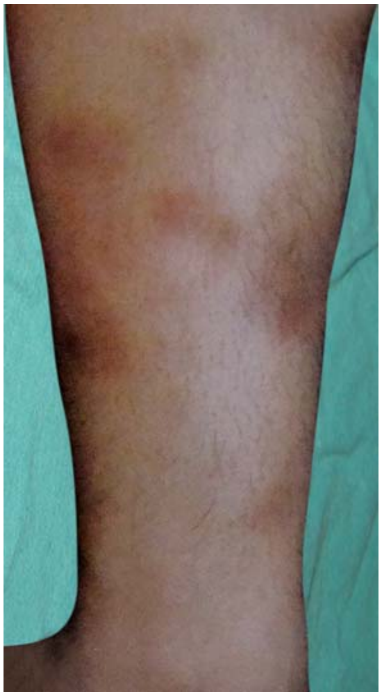

Fig. 22.3: Erythema nodosum. Note the coppery red and raised skin lesions

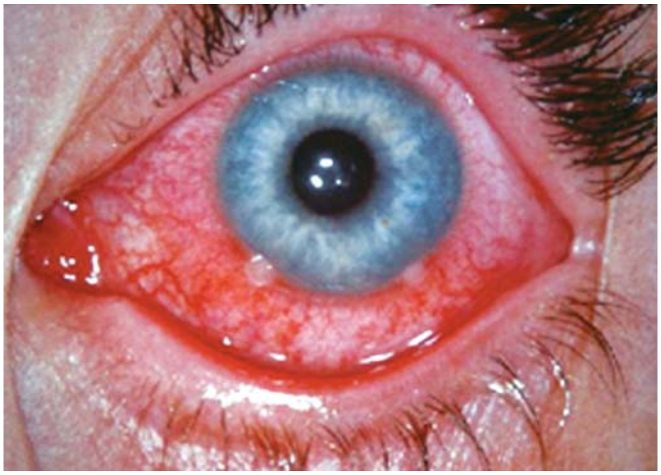

Fig. 22.4: Phlyctenular conjunctivitis

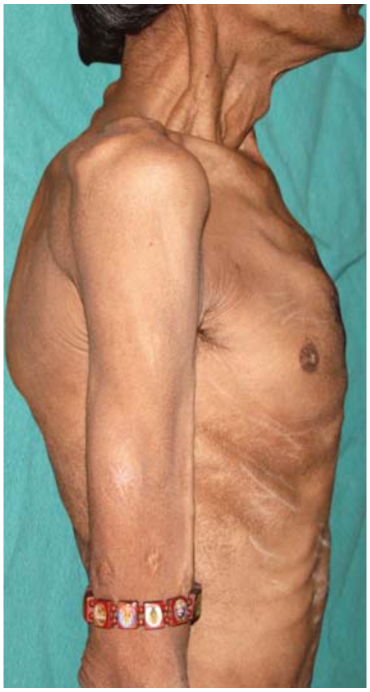

Fig. 22.5: Pectus carinatum (Pigeon chest)

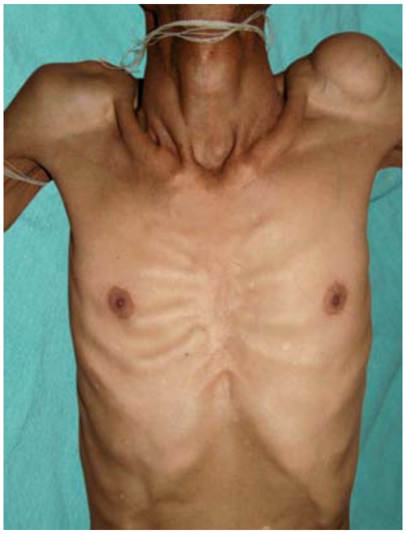

Fig. 22.6: Pectus excavatum (Funnel chest)

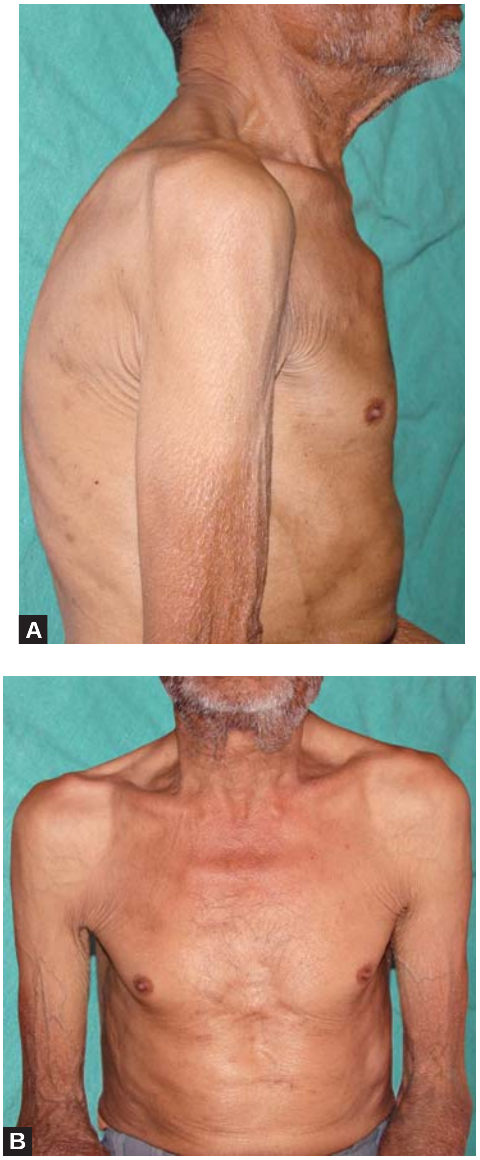
Observe it for any scar, injection mark, stains or lumps as a consequence of disease or trauma. Its shape may be distorted by the disease of ribs, vertebrae or the underlying lungs, pectus carinatum or pigeon chest [localized prominence of sternum and adjacent ribs (Fig. 22.5)], pectus excavatum or funnel chest [localized depression of sternum and adjacent ribs (Fig. 22.6)], kyphosis (forward bending), scoliosis (lateral bending), kyphoscoliosis, flattening (decreased AP diameter), hyperinflation or barrel shaped [increased AP diameter (Figs 22.7A and B)]. Also, look for muscle wasting, if any.

Movements of chest wall: Normally, the two sides of the chest move equally. Decreased or absent movements on one side may indicate disease of chest wall, pleura or of the lung on that side. Symmetrical decrease in the movement of chest wall occurs in emphysema, asthma



Figs 22.7A and B: Barrel-shaped chest

and end-stage diffuse pulmonary fibrosis. Intercostal recession (In-drawing of intercostals spaces) indicates severe upper airway obstruction (laryngeal or tracheal tumor). Inward movement of lower ribs on inspiration (instead of normal outward movement) occurs in emphysema and asthma. Observe for use of alae nasi (pneumonia in childhood) or accessory muscles of respiration (emphysema).

Palpation

Gently begin palpating the part of the chest showing obvious swelling on inspection, or at the site where the patient complains of pain to detect: Inflammatory edema (fractured ribs, cellulitis, infected cysts or tumors), air (subcutaneous emphysema), pus (abscess, empyema necessitans) or nodules (purpura, sarcoid nodule, metastatic nodule). Assess the position of trachea in suprasternal notch and of cardiac impulse at the lower chest wall. Displacement of these structures indicate shift of the mediastinum. Same side shift occurs in collapse or fibrosis, contralateral shift in effusion or pneumothorax. Vocal fremitus is detected by placing the ulnar side of hand, over the patient's chest wall when the patient narrates "one, two, three" or "ninety-nine." It may be done along with vocal resonance at the time of auscultation. A rub or rhonchus may, at times be palpable.

Percussion

Compare the degree of resonance over the equivalent areas on the two sides of chest and then focus on an area of interest to detect the generalized or localized abnormality. Always note for area of tenderness, if any. Different character of percussion note may point to the likely underlying pathology (Table 22.4). Topographical and tidal percussion has practically lost its value in modern clinical practice.

In general, the side of chest, which moves less is pathological (or "more pathological" than the other side). A stony dull percussion note indicates pleural effusion, more so, if the breath sounds and vocal resonance are decreased. A dull note with increased bronchial breath sounds and bronchophony indicates consolidation, but dull note with shrunken chest and decreased breath sounds indicate atelectasis. Hyper resonant note indicates pneumothorax, more so when the chest appears fuller and the breath sounds/vocal resonance are decreased or absent. Pulmonary tumors cause dullness when peripheral, and abut the chest wall, or in the presence of collapse of a lobe or a lung.

Auscultation

Breath sounds: Listen to lung sound for their character and quality on the two sides, on all the lung fields using

TABLE 22.4: Types of percussion note and likely etiology

Type of note	*Underlying object/pathology*
Tympanic	Hollow viscus, pneumothorax
Hyper-resonant	Pneumothorax
Resonant	Normal lung
Impaired to dull	Consolidation/collapse/fibrosis
Stony dull	Effusion/empyema

the diaphragm of stethoscope. Normal vesicular breath sounds (low frequency rustling sound) are best heard at the lung bases throughout inspiration, but a more high pitched sound is heard in early expiration. When the vesicular breathing is blowing in character and loud in mid-expiration, it is called as bronchovesicular. In a normal person, such a breath sound may be heard over either lung apex. Bronchial breathing is a high-pitched blowing sound of higher intensity, heard during inspiration and expiration and separated by a brief pause. It may be normally heard over the trachea or the larynx, but when heard over the chest, usually as a result of consolidated lung, it is abnormal. It is heard due to the increased transmission of high-pitched breath sounds through the chest wall as the solid lung acts as a bridge between the patient's airways and the chest wall. On the contrary, breath sounds are decreased in intensity when fluid (effusion), air (pneumothorax) or atelectasis interferes with the transmission of sounds from airways to the chest wall.

Adventitious sounds: Normal lung fields are devoid of any extra sounds, but extra sounds may be heard in disease states. These include wheezes, crackles and pleural rub. Wheezes are continuous, high-pitched sounds, often musical in character, which arise from air moving in the narrowed airways, e.g. in asthma. They are more marked during expiration and usually associated with prolonged expiratory time. Continuous, but low-pitched sound may be heard at a localized area (rhonchus) such as obstruction of a large airway by a tumor. Crackles are discontinuous, "popping" or bubbling sounds. Coarser, gurgling sounds are caused by secretions in the larger airways, heard during inspiration, as well as expiration. Finer crackles are usually heard during early inspiration. They are commonly heard in the presence of restrictive lung disorders such as the pulmonary edema and pulmonary fibrosis. They may be produced due to sudden opening of the small airways. Rub is a localized cracking or rubbing sound, often associated with chest pain, heard during both inspiration, as well as expiration (to and fro character). It may at times, be felt by the palpating hand. It indicates pleural inflammation. Exclude extraneous or false sounds that may occur due to the movement of stethoscope on skin, hair or clothing, or due to muscle twitching (shivering due to cold).

Vocal resonance: It is the audible perception of the transmitted vibrations from the vocal cords over the chest as the patient narrates "one, two, three" or "ninety nine." Compare each point on one side with the corresponding point on the opposite side. It is increased in the presence of consolidation. The spoken sound may be perceived as if spoken directly into the listener's ear, bronchophony. At times, even when a patient whispers, the sounds may be clearly heard, whispering pectoriloquy. Vocal resonance is decreased (or absent) in the presence of atelectasis or pleural effusion. In the latter, the spoken sound may be perceived as nasal or bleating in character, egophony.

Systemic Examination

Examination of other systems provides vital clues in the assessment of a patient with respiratory illness. Certain skin lesions are an essential part of the pulmonary disease, for example, erythema nodosum in TB and sarcoidosis; Kaposi's sarcoma in AIDS; larva migrans in Loeffler's syndrome; metastatic nodule in lung carcinoma; and "Mat" telangiectasia in Osler-Weber-Rendu disease. Skin lesions may also manifest as the complication of management, e.g. Stevens-Johnson syndrome in a patient of TB on antitubercular treatment, or be a part of a systemic disease having pulmonary manifestations, such as lupus pernio, flashy papules and erythema nodosum in sarcoidosis, malar rash and discoid lesions (often accompanied by telangiectasia, atrophy and scarring) in systemic lupus erythematosus. Besides, certain primary skin diseases like erythema multiforme may have pulmonary complications.

Examination of the joints may show symmetrical arthritis of small joints (rheumatoid arthritis) or large joints (Behçet disease). Examination of cardiovascular system may unravel cor pulmonale complicating the hypoxemia of pulmonary diseases or unravel the underlying pericardial, myocardial, endocardial or valvular lesions of the heart or aneurysmal lesions of vessels that complicate the respiratory diseases. Similarly, examination of abdomen may reveal advanced cirrhosis that leads to hepatopulmonary syndrome, while neurological examination may reveal the signs of metastatic brain lesion in an otherwise occult lung cancer.

Bedside Measurement of Lung Functions

Measurement of forced expiratory time had been used to detect the presence of airway obstruction in a patient at bedside.[14] The length of time taken to walk a known distance is a simple test of lung function.[15] Peak expiratory flow measurements and oxymetry can also be considered as an essential component of initial clinical and physical assessment.

Microbiological Approach to Respiratory Infections

Pallab Ray

UPPER RESPIRATORY TRACT INFECTIONS

Bacterial infections of the upper respiratory tract vary from benign pharyngitis to life-threatening epiglottitis. Infections can be divided into syndromes involving the nasal cavity and its extensions, including the sinuses, the middle ear and the associated tissues.

Normal Flora of the Upper Respiratory Tract

The upper respiratory tract is colonized with a host of organisms. The paranasal sinuses are normally sterile. The anterior nares are colonized by staphylococci, micrococci and corynebacterium species.[1] Continuous evaporation of tear draining into nasal cavities raises the salt concentration locally, favoring colonization by salt-resistant staphylococci, including *Staphylococcus aureus*. The nose is the primary site of carriage of *S. aureus* in nearly a third of the healthy population. The nasopharynx has a more complex flora comprising of resident and transient flora. The resident flora comprises of streptococci (viridans group), *Neisseria* species, members of family *Enterobacteriaceae* and anaerobes, including *Bacteroides* species and *Fusobacterium* species.[2] Additionally, all individuals are transiently colonized by one or more potentially pathogenic bacteria that include group A streptococcus (less frequently groups B, C and G), *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis* and *Moraxella catarrhalis*.

The Common Cold

Common cold is an upper respiratory syndrome caused by a variety of viral pathogens. The significance of common cold originates from the sheer frequency of these illnesses in the general population. Although generally mild and self-limited, these illnesses are associated with an enormous economic burden both in lost productivity and in expenditures for treatment.

Etiology

Rhinoviruses cause approximately one half of all colds. More than 100 serotypes and short-lasting serotype specific immunity results in repeated infections with seasonal predominance in the community. Other important pathogens include the coronaviruses and Respiratory Syncytial Virus (RSV). Influenza, parainfluenza and adenoviruses are often associated with cold-like symptoms though these agents primarily cause lower respiratory or systemic symptoms. Recently identified causes, though uncommon, include metapneumovirus, detected in 2001,[3] and bocavirus, a human parvovirus discovered in respiratory secretions in 2005.[4]

Laboratory Findings

Routine laboratory studies are not helpful for the diagnosis and management of the common cold. A nasal smear for eosinophils may help to differentiate allergic rhinitis from a viral etiology. A neutrophilic predominance in nasal secretions is rather characteristic of uncomplicated colds and does not necessarily indicate bacterial superinfection. Though it is possible to establish the viral etiological agent of common cold by culture, antigen detection and molecular or serologic methods, the lack of therapeutic relevance generally precludes the necessity of the same. Bacterial cultures or antigen detection is indicated only when group A *Streptococcus* (GAS), *Bordetella pertussis*, or nasal diphtheria is suspected. The isolation of other bacterial pathogens is not an indication of bacterial nasal infection.

Pharyngitis

Acute pharyngitis classically presents as sore throat, fever and pharyngeal inflammation characterized by redness and edema, frequently with vesicles or ulcerations.[5] It affects all age groups though children are more frequently affected with higher incidence during winter and spring in temperate climates and transitional seasons in tropical climates. Besides pharyngitis as a primary entity, sore throat and pharyngeal erythema may be associated with systemic disorders, such as the acute retroviral syndrome, or part of a more generalized upper respiratory tract infection.

Etiology

Most cases of acute pharyngitis are due to viral infections, and are usually benign, self-limited illnesses. Viruses account for up to one half of all cases, often associated with other signs or symptoms of upper respiratory tract infection.[6] All viruses implicated in upper respiratory tract infections have been implicated in causation of pharyngitis. Adenovirus is considered as the most common viral cause of pharyngitis, reported in 12 to 23% of cases.[7] Other respiratory viruses that cause pharyngitis include rhinoviruses, coronaviruses, enteroviruses, influenzavirus A and B, parainfluenza viruses, RSV, coronaviruses, Human Metapneumovirus (hMPV), and human bocavirus.[8] Human Merpesviruses, such as Epstein-Barr Virus (EBV), Herpes Simplex Virus (HSV), Human Immunodeficiency Virus Type 1 (HIV-1) and human cytomegalovirus have been infrequently reported to cause pharyngitis.

A child in the age group of 5 to 15 years suffers from an average of seven episodes of sore throat in a year, of which six are viral and one is streptococcal.[9] *Streptococcus pyogenes*, also known as Lancefield GAS or Group A Beta Hemolytic Streptococcus (GA-BHS), is the commonest bacterial etiological agent of highest concern because of its associated nonsuppurative sequelae, acute rheumatic fever and post-streptococcal glomerulonephritis. Group A streptococcus is responsible for approximately 10 to 15% of cases of pharyngitis in adults[10] and 15 to 30% of cases in children.[9,11] Developing countries have reported a recent trend of emergence of streptococcus group C and G in pharyngeal carriage and infection.[12] *Arcanobacterium haemolyticum* is a rare cause of bacterial pharyngitis, especially in adolescents and young adults.[13] *Fusobacterium necrophorum*, a gram-negative, nonspore-forming anaerobe, is a bacterial cause of sore throat in about 10% of cases of pharyngitis, distinctive by its frequent recurrences.[14] *Corynebacterium diphtheriae* is a cause of pharyngitis and diphtheria in countries without adequate coverage of primary immunization.[15,16] Rare causes of bacterial pharyngitis include *Neisseria gonorrhoeae* in sexually active adolescents and young adults, *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae*.[7]

Diagnosis

Pharyngitis is one of the most common causes for seeking medical attention. Differentiation of bacterial etiology from viral is important for the substantially higher morbidity of the former, serious nonsuppurative sequelae associated with GAS infection and to avoid unnecessary antibiotic therapy in viral cases. In GAS pharyngitis, the risk of development of rheumatic fever or post-streptococcal glomerulonephritis is directly proportional to the delay in the institution of therapy. Symptoms, such as conjunctivitis, coryza, oral ulcers, cough and diarrhea suggest a viral cause. On the other hand, abrupt onset, presence of tonsillar or pharyngeal exudates, tender anterior cervical lymphadenopathy, and fever are more commonly associated with GAS infection. Many clinical prediction rules have been proposed to help differentiation GAS from viral pharyngitis. Scoring systems use clinical and epidemiologic pointers to a quantitative probability that favors GAS over a viral etiology.[17] The clinical predictive efficacy of these scoring protocols are limited by extensive overlap of the signs and symptoms of many viral causes of acute pharyngitis with those of infections caused by GAS. Consequently, the Infectious Disease Society of America, the Committee on Infectious Diseases of the American Academy of Pediatrics, and the American Heart Association recommend guidelines that include confirmation of GAS infection by Rapid Antigen Detection Test (RADT), throat culture, or both.[18] In contrast, the guidelines issued by the Centers for Disease Control and Prevention and the American College of Physicians–American Society of Internal Medicine suggest empirical treatment based on a pharyngitis score alone with or without microbiologic confirmation.[19]

The differences in these guidelines have been debated, and empirical therapy based on these clinical prediction rules has been implicated in the overuse of antibiotics for treatment of pharyngitis.[17] A study of the effectiveness of these strategies concluded that microbiologic confirmation was the most effective and least expensive when all factors were considered.[20]

Confirmation of GAS by throat swab culture on sheep blood-agar plate is the most widely accepted practice for diagnosing streptococcal pharyngitis. Selective streptococcal media, less often used, inhibit contaminating normal flora and increase the sensitivity and specificity of culture for GAS,[21] with the attending risk of inhibiting other bacterial etiologic agents. Specimens should be obtained from bilateral tonsillar surfaces and the posterior pharynx while avoiding the mouth and other surfaces of the pharynx. The major disadvantage of culture for the confirmation of GAS pharyngitis is the time period of 24 to 48 hours required for accurate detection. Rapid antigen detection tests have become widely available and the sensitivity and specificity compares well with those of culture. Rapid results help in timely treatment, help to reduce the spread of GAS and antibiotic abuse in viral pharyngitis, and, most importantly, minimize suppurative and nonsuppurative sequelae of GAS. Newer assays use molecular biology methods to detect DNA specific to GAS by chemiluminescence or real-time Polymerase Chain Reaction (PCR), but are restricted because of the need to batch specimens and the specialized equipment required. On a properly collected specimen, the sensitivity of RADTs is 70 to 90% compared with culture, with a specificity of approximately 95%.[22] A negative RADT result, in a child with high index of suspicion for GAS infection, should be confirmed by culture.[23] Culture on either standard blood-agar plate or selective streptococcal media will isolate both group C and G streptococci; however, identification needs further characterization and serogrouping. *Arcanobacterium haemolyticum* also grows on standard blood-agar or selective streptococcal media, but may take as long as 72 hours to grow as small and dry colonies.

Confirmation of pharyngitis, caused by other bacterial agents, requires high degree of clinical suspicion and use of specific media and techniques. If diphtheria is suspected, the laboratory must be informed so that tellurite containing selective and differential media, not routinely used, are used for isolation. Recently, multiplex PCR has been used for the identification of *Corynebacterium diphtheriae* and to differentiate toxin producing from nontoxigenic strains.[24] *Fusobacterium* pharyngitis demands special technique for the isolation of anaerobic bacteria. The diagnosis of pharyngitis caused by *N. gonorrhoeae* is confirmed by culture on selective gonococcal media like modified Thayer-Martin medium.

Pharyngitis caused by *M. pneumoniae* or *L. pneumophila* requires serologic testing demonstrating rising titers in paired, acute and convalescent, serum samples; however, PCR and culture are commonly used in addition to serology for research purposes in advanced laboratories. The diagnosis of EBV infection is also confirmed by serology, by a heterophile antibody test (Monospot® or Monoslide®) or detection of immunoglobulin M antibodies to EBV viral capsid antigen. Common respiratory viruses that cause pharyngitis can be identified by either viral culture of a nasopharyngeal swab or molecular detection techniques such as PCR or reverse transcriptase-PCR.

Acute Laryngitis

Acute laryngitis is a not-so-uncommon clinical condition, usually mild and self-limiting. The symptoms include recent onset of hoarseness or a husky voice often associated with dry cough.[25] Similar symptoms are frequently associated with an upper respiratory tract infection, rhinorrhea and sore throat.

All the major respiratory viruses have been known to cause laryngitis, the commonest being parainfluenza virus in one-fifth of the cases. Less frequent agents include the rhinoviruses, influenza virus, the parainfluenza viruses, coronavirus, adenovirus and human metapneumovirus.[26,27] Bacterial respiratory infections have been associated with acute laryngitis. Hoarseness is often associated with acute streptococcal pharyngitis and diphtheria, the latter especially in the developing world. Tubercular laryngitis is a frequent association with tubercular lung infection.[28] The possible etiologic roles of *Moraxella (Branhamella) catarrhalis* and *H. influenzae* in acute laryngitis has been suggested, but remains to be proven. Uncommon causes of acute laryngitis include herpesviruses, parvovirus B19, mucosal candidiasis, *Coccidioides immitis, Cryptococcus neoformans, Sporothrix schenckii,* and group G betahemolytic streptococci in normal and immunocompromised patients.[29] Hoarseness may also be noted as a component of other laryngeal infections such as croup, acute epiglottitis or supraglottitis.

Acute Laryngotracheobronchitis (Croup)

Croup is a childhood viral infection of the upper and lower respiratory tracts resulting in inflammation in the subglottic area and manifesting as dyspnea with characteristic stridor on inspiration. The term “croup” is derived from an Anglo-Saxon word “kropan” or the old Scottish term “roup,” which meant “to cry out in a shrill voice.”

Etiology

The predominantly viral etiology of croup has been established with recent molecular diagnostic techniques, including Reverse Transcriptase Polymerase Chain Reaction (RT-PCR), with the parainfluenza type 1 virus causing one-fourth to one-third of cases followed by parainfluenza type 3 as the second most common agent. Other agents, less frequently incriminated include the influenza virus, rhinoviruses, enteroviruses, bocavirus, adenoviruses, hMPV, *M. pneumoniae*, human coronavirus and measles virus.[30]

Diagnosis

The diagnosis of croup is primarily clinical and epidemiological. Identification of the specific viral agent is usually unnecessary, and obtaining respiratory tract swabs and secretions is more likely to augment the child's respiratory distress than yield clinically relevant information.

Otitis Externa

Infection of the external auditory canal (otitis externa) resembles those of skin and soft tissue elsewhere and the microbial flora of the external auditory canal resembles flora of skin elsewhere, predominantly composed of *Staphylococcus epidermidis*, *S. aureus*, corynebacteria, and *Propionibacterium acnes*.[31] Otitis externa may be subdivided into acute localized otitis externa, acute diffuse otitis externa, chronic otitis externa and malignant otitis externa, and the causative organisms include those of the normal skin flora and *gram-negative bacilli,* particularly *Pseudomonas aeruginosa*.

Otitis Media

Acute otitis media (AOM) is an acute illness characterized by inflammation of the mucosa lining the middle ear with exudation. Otitis Media with Effusion (OME) is characterized by fluid in middle ear without signs of acute inflammation of the middle ear mucosa.

Microbiology

The bacteriology of otitis media documented by the cultures of middle ear effusions obtained by needle aspiration has implicated the importance of *S. pneumoniae* and *H. influenzae* in all age groups, but more recent studies, since the introduction of the pneumococcal conjugate vaccine in developed countries, suggest that *H. influenzae* may replace pneumococcus as the most frequently isolated pathogen of AOM in children.[32] *S. pneumoniae* is the most important bacterial cause of otitis media in most parts of the world. Otitis media caused by *H. influenzae* is associated with nontypeable strains in majority of patients whereas *H. influenzae* type b causes 10% of cases, which are frequently severe and accompanied by bacteremia or meningitis.

M. catarrhalis has been isolated from approximately 10% of children with AOM[33] and is usually associated with a mild form of disease. Most strains produce beta-lactamase and are resistant to penicillin G, ampicillin and amoxicillin. *S. aureus*, including methicillin and multi-drug-resistant strains, is an uncommon cause of AOM. During the preantibiotic era, GAS was a frequent cause of severe AOM, frequently complicated by mastoiditis and often associated with scarlet fever, but the entity has become rare in the last two decades. Chronic suppurative otitis media cases frequently yield *P. aeruginosa*, *S. aureus* and *aerobic gram-negative bacilli* on culture.[34]

Viral infection is frequently the initial event in the development of acute otitis media.[35,36] Respiratory viruses have been isolated from one fourth of middle ear fluids of children with AOM. Respiratory syncytial virus, influenza virus, enteroviruses, coronaviruses and rhinoviruses were the most common viruses.[36] Combined viral and bacterial infections are frequent and may be more severe than bacterial infection alone.[35]

Mastoiditis

Most cases of AOM with fluid in the middle ear space is associated with inflammation of the mastoid air cells. Clinically significant mastoiditis has been rare since the introduction of antimicrobial agents. Infection in the mastoid usually follows middle ear infection. The bacteriology of mastoiditis is the same as that of AOM, including *S. pneumoniae* and *H. influenzae* as the major pathogens. Patients with prolonged perforation of the tympanic membrane may have invasion of organisms from the ear canal, including *Pseudomonas* spp. Polymicrobial flora is commonly isolated from the cases of chronic mastoiditis in developing countries.[37] Cultures for bacteria from ear drainage fluid must be taken with care to distinguish fresh drainage fluid from material in the external canal. The canal must be cleaned and fresh pus, free of contamination from external canal, obtained. If the tympanic membrane is intact, tympanocentesis should be performed to obtain material from the middle ear.

Sinusitis

Sinusitis may be classified as acute or chronic. Because most cases of acute bacterial sinusitis are secondary to viral infection of the upper respiratory tract or allergic inflammation, nasal inflammation is commonly associated justifying the commonly used term as rhinosinusitis. The preferred term is acute community-acquired bacterial sinusitis.[38,39]

Microbiology

The paranasal sinuses are sterile under normal conditions, unlike the nasal passages, which are heavily colonized with bacteria. Reliability of knowledge of the microbiology of acute community-acquired sinusitis is dependent on proper specimen collection. The nasal cavity is heavily colonized with commensal flora that easily contaminates specimen from the paranasal sinuses. Reliable specimens of sinus secretions have been obtained by puncture of the maxillary antrum, to reduce the risk of nasal contamination. To further discriminate true infection from contamination, quantitative methods have been used to enumerate the microbial load. Attempts have been made to define infection as a bacterial load of 10^4 Colony-Forming Units per Milliliter (CFU/ml) of aspirated material.[39] Cultures obtained from the middle meatus adjacent to the sinus ostia collected by swab or aspiration via an endoscope have been compared to those obtained by sinus aspiration. This is associated with a high risk of contamination of the endoscope while negotiating through the nonsterile anterior nasal cavity. Most studies using endoscopic middle meatal culture in adult patients show a sensitivity of approximately 80%, a specificity of 90%, a positive predictive value of 80 to 90%, and a negative predictive value of 80 to 90%, with maxillary sinus aspiration considered the gold standard.[40]

In community-acquired bacterial sinusitis, *S. pneumoniae* is the most frequently isolated organism, followed by nontypeable *H. influenzae* and *M. catarrhalis*. Streptococci, *S. aureus,* and anaerobes are isolated less frequently.[41] In children, *M. catarrhalis* is isolated with a greater frequency than in adults. Widespread immunization with pneumococcal conjugate vaccine, in several countries, has diminished the frequency of *S. pneumoniae* with a consequent shifting of the serotypes[42] and a relative increase in the isolation of *H. influenzae*.

Viruses have been infrequently isolated from patients with acute sinusitis. This may reflect the delay in the timing of sampling, done after the patient has been symptomatic for a week, when the viral infection may have waned or overshadowed by secondary bacterial pathogens. Respiratory viruses, such as adenovirus, parainfluenza and rhinovirus have been recovered from approximately 10% of sinus aspirates. Fungi have long been recognized as important pathogens in selected patients with acute or chronic sinusitis.

Nosocomial sinusitis is a frequent complication, particularly in critical care setting affecting between 7.7 to 32% of patients.[43] Nasal intubation has a risk factor for this infection. Gram-negative organisms, including *P. aeruginosa* and *S. pneumoniae* are frequently isolated in patients with nosocomial sinusitis.

Epiglottitis

Acute epiglottitis is a cellulitis of the epiglottis and adjacent structures leading, in some cases, to sudden airway obstruction. *H. influenzae* type B is the most frequent pathogen isolated from epiglottis in pediatric patients and in up to one-fourth of adult patients.[44] Other agents occasionally implicated include *S. pneumoniae*, staphylococci and streptococci.[45] The role of viruses in epiglottitis, other than possibly herpes simplex infections (rarely) has not been established.

LOWER RESPIRATORY TRACT INFECTIONS

Acute Bronchitis

Acute bronchitis refers to a clinical syndrome distinguished by a relatively brief, self-limited inflammatory process of large and mid-sized airways, not associated with pneumonia on chest radiograph.

Microbial Etiology

Acute bronchitis is most commonly caused by a wide range of viruses. Approximately 10% of cases are attributed to bacterial pathogens, including *M. pneumoniae, C. pneumoniae,* and *B. pertussis*. The relative prevalence of different pathogens varies according to age, season and the reliability of the diagnostic methods used. Molecular tests, contrary to conventional culture, identify a wider range of viral pathogens, especially in adults, that include RSV, adenovirus, hMPV and parainfluenza viruses.[46] Influenza A and B viruses are commonly associated with winter outbreaks of acute bronchitis.[47] Coronavirus, rhinoviruses, echovirus, coxsackievirus and strains of Severe Acute Respiratory Syndrome (SARS), can cause acute bronchitis. Bacteria contribute to a minority of cases and the agents include *M. pneumoniae*, *C. pneumoniae*, *B. pertussis* and *Bordetella bronchiseptica*.[47,48]

Diagnosis

Etiologic diagnosis depends on laboratory confirmation. Rapid antigen detection in nasopharyngeal swabs is relatively sensitive for influenza virus and RSV. Identification of other viral pathogens (RSV, hMPV, coronaviruses and parainfluenza viruses) requires tissue culture or RT-PCR assay. Diagnosis of *M. pneumoniae* depends on demonstrating specific IgM in serum or PCR. *B. pertussis* diagnosis can be made by serology, PCR, or culture. *C. pneumoniae* is difficult to diagnose and requires PCR or serology.

Bronchiolitis

Bronchiolitis, variously named as "acute catarrhal bronchitis," "interstitial bronchopneumonia," "spastic bronchopneumonia," "capillary or obstructive bronchitis," and, more commonly, "wheezy bronchitis" and "asthmatic bronchiolitis", is the most common acute viral lower respiratory tract illness occurring during the first two years of life.

Etiology

Respiratory syncytial virus is the cause of about two-third of the cases of bronchiolitis.[49,50] Other viruses include hMPV, the parainfluenza viruses, influenza, rhinoviruses, human non-SARS virus, coronaviruses and human bocavirus.

Viral agents of upper respiratory tract infections, rhinoviruses and enteroviruses, also are commonly isolated from specimens from children with bronchiolitis. Role of these viruses as primary agents causing bronchiolitis or as coinfecting agents is uncertain.

Diagnosis

Laboratory determination of the specific etiology of bronchiolitis usually is unnecessary and therapeutically irrelevant. Rapid virologic diagnosis may be epidemiologically useful for the implementation of appropriate infection control procedures or, in selected cases with high-risk conditions or severe illness with influenza or RSV, for determination of specific antiviral therapy. The specific agent of bronchiolitis can be identified by viral isolation from a nasal wash using shell vial culture techniques. Rapid viral antigen techniques, including immunofluorescent assays, optical immunoassays and enzyme immunoassays are technically nondemanding, cost effective and rapid.[51] These assays are available for RSV, parainfluenza viruses, influenza viruses, and hMPV and many of these commercially available antigen assays allow the simultaneous detection of multiple agents.

The use of molecular diagnostic assays, including RT-PCR has enhanced the sensitivity and specificity of the detection of the respiratory viruses associated with bronchiolitis,[51,52] but they are expensive, and are not usually easily available in developing countries.

Acute Pneumonia

Pneumonia, designated by Sir William Osler as the "Captain of the Men of Death." is among the top ten most common causes of death among all age groups in the United States, the sixth leading cause of death in those 65 years or older, and the single most common cause of infection-related mortality.[53] An understanding of the pathogenesis of the disease, evaluation of relevant data from a careful history and physical examination, recognition of common clinical patterns of infection, and information from the microbiology laboratory all aid in narrowing down the possible etiologic agents of pneumonia, thereby allowing reasonable therapy to be selected empirically.

Acute Community-Acquired Pneumonia

A long list of bacterial, fungal, viral and protozoal agents may cause pneumonia. *Streptococcus pneumoniae* is undoubtedly the commonest cause of acute community-acquired pneumonia in developing countries, accounting for one-half of the cases though reliable reports of its actual prevalence are not available.

Acute Respiratory Infections (ARI) are leading causes of high morbidity and mortality in infancy and childhood in developing countries. Such respiratory infections are reported to kill 4 million children every year worldwide, while in India, they account for 14.3% of deaths during infancy and 15.9% during early childhood.[54,55] Of all upper and lower respiratory tract diseases, pneumonia is the most important cause of death accounting for about 3 million deaths in children worldwide. In United States alone, pneumonia rank as the sixth leading cause of death while in India, it is the number one killer disease.[56] Annually 94 out of every 1,000 Indian children develop pneumonia and account for 12 to 15% of deaths.[57]

Pneumonia is a disease caused by a wide variety of microorganisms and has a spectrum of severity that ranges from mild illness to severe disease associated with a high mortality rate. *Streptococcus pneumoniae* is the commonest pathogen though the relative incidence is rapidly coming down with the implementation of pneumococcal vaccination in developed nations. An estimated 3 to 38% of cases of acute community-acquired pneumonia are caused by *H. influenzae*.[58] In developed countries, the use of the *H. influenzae* conjugate vaccine has decreased the incidence of invasive disease caused by *H. influenzae* type B, with a consequent increased incidence of invasive disease, including pneumonia caused by nontypeable strains.[59]

Classically, *S. aureus* has accounted for 2 to 5% of acute community-acquired pneumonia cases[60] commonly in older adults and in those with influenza. Although pneumococcus still represents the most common etiologic agent, staphylococcal disease occurs with a higher frequency than that noted in non–influenza-related, community-acquired pneumonia. In 2002 many cases of community-acquired pneumonia caused by *S. aureus* were described in France.[61] Acute Respiratory Distress Syndrome (ARDS) was a frequent complication of infection and mortality rates were higher than in patients with pneumonia caused by *S. aureus* without the Panton-Valentine Leukocidin (PVL). Similar disease patterns have been described in the United States with these strains of Community-Acquired of Methicillin-Resistant *Staphylococcus aureus* (CA-MRSA).[62] These CA-MRSA pneumonias are associated with severe pneumonia with mortality rates of 29 to 60%. CA-MRSA pneumonia has therefore become an important entity to consider in the right clinical setting.

Aerobic gram-negative bacteria and mixed aerobic and anaerobic infections cause most of the remaining cases of acute community-acquired pneumonia. Gram-negative rods may cause 7 to 18% of pneumonia cases. *Klebsiella pneumoniae, P. aeruginosa* and *Enterobacter* species are the most often isolated organisms.[63] Gram-negative bacilli are particularly important pathogens in older adults, especially those with chronic underlying disease and those who are bedridden and recently hospitalized. *Pseudomonas* infection should be suspected in patients with pulmonary comorbidities and recent hospital stays.

Indian investigations have reported *S. pneumoniae* and *H. influenzae* as the most commonly involved organisms in community-acquired pneumonia.[64,65] In a study from Shimla,[66] 70 cases of CAP were studied by culture of sputum, blood and pleural fluid and IgM Enzyme-Linked Immunosorbent Assay (ELISA) for *M. pneumoniae*. An etiological agent was identified in 53 (76%) cases of which 41 (77%) were monomicrobial and 12 (23%) had a mixed etiology. *Streptococcus pneumoniae* was the commonest (36%) agent followed by *K. pneumoniae* (22%), *S. aureus* (17%) and *M. pneumoniae* (15%). The role of *M. pneumoniae* in the causation of CAP has been variably reported from various studies in India. One study from Delhi[67] showed evidence of *M. pneumoniae* infection in 36% (10% definitive and 26% probable) of 62 adults studied using IgM ELISA, Gelatin Particle Agglutination Test (GPAT) and antigen detection by immunofluorescence; another study from same place has shown *M. pneumoniae* responsible for 27% of 62 children with CAP.[68] There was evidence of *Chlamydia pneumoniae* in 6% of the children with CAP. From the South, incidence of *M. pneumoniae* have been shown to be 24% amongst children with CAP in Manipal[69] and 30% amongst children with CAP from Vellore.[70] The serological evidence of *Legionella pneumophila* infection was reported in 60 hospitalized cases of CAP.[71]

Legionella species are the most important water-related pulmonary pathogens in the United States with regard to mortality and morbidity. The importance of *Legionella* species in causing pneumonia has varied greatly in different geographic areas, with incidences ranging from 2 to 30%.[72] *Moraxella catarrhalis* has also been identified as a cause of pneumonia.[73] The overall incidence of disease caused by this bacterium is low, but it is an important pathogen in older adults with COPD and various forms of immunosuppression.

Pneumonia is the second or third most common reason for hospitalization in people who are 65 years old and above; and represents a major cause of morbidity and mortality. In some series, pneumonia represents the leading cause of death in this population. In general, the cause of community-acquired pneumonia in the older population follows the general trend of infection in younger populations. *S. pneumoniae* is the predominant organism, accounting for more than half of the cases. *H. influenzae*, mostly nontypeable, is the second most common agent; accounting for up to 10% of episodes.[74] The incidence of other aerobic gram-negative bacilli in causing pneumonia in older adults is variable because the criteria for diagnosis of true pneumonia versus colonization vary. Increased oropharyngeal colonization with aerobic gram-negative bacilli has been documented in the older population. Colonization is an outcome of debility, prior use of antibiotics, decreased activity, diabetes, alcoholism, and incontinence and is thought to be a risk factor of development of pneumonia caused by these organisms.[75] Older adults are at greater risk for infection with group B streptococci, *M. catarrhalis* and *Legionella* species, although the overall incidence of these agents in the older population is relatively low.[73] Polymicrobial infections and pneumonia due to aspiration occur more frequently in older adults.[76] With the development of sensitive nucleic acid amplification tests, the role of viruses as a cause of pneumonia is being more clearly defined.[77] Recent studies have suggested a viral etiology in 15 to 29% of all patients hospitalized with pneumonia with significantly more viral infections noted in the older age groups (median age of 76).[77,78]

Influenza is consistently the most commonly isolated virus usually followed by RSV, human metapneumovirus, parainfluenza virus, enterovirus and coronavirus.

The cause of community-acquired pneumonia in patients with AIDS has changed significantly since the beginning of the epidemic. *Pneumocystis jiroveci (carinii)* remains the most frequent AIDS-defining opportunistic pneumonia in the United States and the rest of the world, although Highly Active Antiretroviral Therapy (HAART) and effective prophylactic strategies have more than halved the incidence of *P. jiroveci* pneumonia and its associated mortality. Bacterial pneumonia has a ten times higher incidence in HIV-positive versus HIV-negative cohorts.[79] The rate of invasive pneumococcal disease may be three times greater in HIV-infected patients than in non–HIV-infected controls.[80] *H. influenzae* and *S. aureus* are also important pathogens.[80,81] A variety of other bacteria have been implicated, including *Rhodococcus equi, Escherichia coli, Serratia species* and *P. aeruginosa.* Infections with *Pseudomonas* are associated with the late stages of disease with *Mycobacterium tuberculosis,* nontuberculous mycobacteria, *C. neoformans* and cytomegalovirus playing important roles as etiologic agents.[82]

Health Care-Associated Pneumonia

An increasing number of patients present to hospital services with pneumonia following contact with various types of the health care institutions, resulting in a blurring of the distinction between community-acquired and nosocomial pneumonia. Health care-associated pneumonia now represents a new syndrome, a hybrid of community-acquired pneumonia and hospital-associated pneumonia.[83] Patients with a history of hospitalization within 90 days prior to developing pneumonia; patients attending hemodialysis clinics; patients receiving intravenous therapy, wound care, or chemotherapy at home; and residents of long-term care facilities or nursing homes are the most likely involved. *S. aureus,* including MRSA; aerobic gram-negative bacilli, including *P. aeruginosa*; and mixed aerobic-anaerobic pathogens associated with aspiration have been most commonly reported.

Atypical Pneumonia Syndrome

Atypical pneumonia classically presents with a mild respiratory tract illness followed by pneumonia with dyspnea and cough without sputum, an atypical chest X-ray and a negative routine culture of sputum specimen. Atypical pneumonia in its typical form is rarely encountered today. *M. pneumoniae, C. pneumoniae, L. pneumophila*, and respiratory viruses are the most significant causes of atypical pneumonia. Other agents, such as *Chlamydophila psittaci, Francisella tularensis, M. tuberculosis* and *Coxiella burnetii* may also cause atypical pneumonia. In patients with AIDS, *Pneumocystis* and nontuberculous mycobacteria should also be included. The difficulty in identifying the various etiologic agents associated with atypical pneumonia has made estimates of incidence difficult. *M. pneumoniae* may account for 10 to 30% of cases of community-acquired pneumonia.[84] *C. pneumoniae* has emerged as an important cause of atypical pneumonia and may account for approximately 6 to 20% of community-acquired pneumonia cases.[85] Of the viral agents associated with atypical pneumonia in adults, influenza A and B, adenovirus types 3, 4, and 7 (especially in military recruits), human metapneumovirus,[77] RSV (especially in older adult and immune-suppressed patients), and parainfluenza virus are the most common.[78,86]

Aspiration Pneumonia

The bacteriology of aspiration pneumonia reflects the flora of the oropharynx, and presence of periodontal disease. Anaerobic bacteria alone are involved in half of cases[87] and in combination with aerobes in other cases.[88] *Bacteroides* species, *Porphyromonas species*, *Prevotella melaninogenica, Fusobacterium species* and anaerobic gram-positive cocci are the predominant anaerobes isolated. In community-acquired aspiration pneumonia, *Streptococcus species* and *H. influenzae* are the most common aerobic isolates.[87] *M. catarrhalis* and *Eikenella corrodens* may also be involved. In contrast, gram-negative bacilli (including *P. aeruginosa*) and *S. aureus* are the most commonly isolated aerobes from nosocomial aspiration pneumonia, including ventilator-associated pneumonia.[87]

Nosocomial Pneumonia, Hospital-acquired Pneumonia, Ventilator-associated Pneumonia

Nosocomial pneumonia is the second leading type of nosocomial infection and accounts for 13 to 18% of all such infections. It is the leading cause of infection-related deaths in hospitalized patients with an attributable mortality of 33 to 50%.[89] Higher mortality rates have been observed when patients are bacteremic or have pneumonia caused by *P. aeruginosa* or *Acinetobacter* species. Ventilator-associated pneumonia (VAP) has been accepted as an important subcategory of nosocomial pneumonia.

Approximately 60 to 75% of cases of nosocomial pneumonia are caused by aerobic gram-negative bacilli, with members of the family Enterobacteriaceae (*K. pneumoniae, E. coli, Serratia marcescens, Enterobacter* species), *Acinetobacter* species and *Pseudomonas* species accounting for the majority of these. *Staphylococcus aureus* causes 13 to 40% of nosocomial pneumonia and appears to be more common in burn units, in patients with wound infections, and in patients recently ventilated after neurosurgery or head trauma.[90] MRSA and Multidrug-resistant (MDR) organisms now play major etiologic roles. In contrast to its prominent role in community-acquired pneumonia, *S. pneumoniae* causes only 3 to 20% of nosocomial pneumonias in most studies and is associated with infection developing early in the hospital course. Anaerobic bacteria have been isolated in up to 35% of the cases of nosocomial pneumonia, although usually less than 5% of infections are thought to be caused by these organisms. They play a role when aspiration is likely to have occurred. Pneumonia caused by *Legionella* species may occur sporadically or as part of outbreaks.

Pleural Effusion and Empyema

Microbiology

In the preantibiotic era, *S. pneumoniae* accounted for 60 to 70% of cases, *Streptococcus pyogenes* for 10 to 15% of cases, and *S. aureus* for 5 to 10% of cases. *S. pneumoniae* more recently accounts for less than 10% of cases and many infections are mixed, with anaerobes present in up to 75% of empyemas as sole organisms or in combination with other aerobic or facultative organisms.[91,92] Bartlett and Finegold found that pleural empyema was caused by aerobic bacteria in 24%, anaerobic bacteria in 35%, and both aerobic and anaerobic bacteria in 41% of 83 medical service patients without prior antibiotic therapy or surgical procedures.[93] The most common anaerobes isolated include the *Bacteroides fragilis* group, *Prevotella species, Fusobacterium nucleatum,* and *Finegoldia species.* Recently, there has been a shift from conventional pathogens to the *Streptococcus anginosus* group in community-acquired empyema in patients with comorbidities.[93] Hospital-acquired empyemas include more staphylococcal infections and gram-negative organisms.

Predisposing factors and associated comorbidities are important pointers to the most likely pathogens. Pneumonia continues to be the most frequent predisposing factor in the development of empyemas. Otherwise healthy adults with pneumonia, the most common bacteria causing empyema are *S. aureus* and *S. pneumoniae.* The incidence of a parapneumonic effusion in hospitalized patients is estimated to be 40%. Empyema caused by *S. aureus, S. pneumoniae* or *H. influenzae* has been common in children. Most cases of *S. aureus* empyema result from *S. aureus* pneumonia with a tendency to cause cavitation, most often seen in older hospitalized patients with underlying medical problems. In developing countries, tuberculous effusions are common, and they can be secondary to a primary infection or more frequently occur as a reactivation tuberculosis. Factors predisposing to aspiration, such as altered mental status, alcoholism and periodontal disease, are common in patients with anaerobic infections of the pleura. Many of these cases tend to be polymicrobial. In addition to anaerobes, viridans group streptococci, aerobic gram-negative bacilli, and occasionally *S. aureus* have been recovered. Pleuropulmonary actinomycosis can result from aspiration leading to a chronic pulmonary infection with chest wall involvement. Nocardia infections occur more frequently in patients with underlying conditions, such as organ transplantation, malignancy, diabetes mellitus, Acquired Immunodeficiency Syndrome (AIDS) and long-term use of steroids. Pleural effusions can develop in up to 50% of patients with nocardiosis.

Laboratory Diagnosis

Aspirated pleural fluid should be sent to the microbiology laboratory for a Gram stain and for aerobic and anaerobic cultures. Using conventional methods achieve a bacterial diagnosis in approximately 60% of pleural fluid samples.[94] The low detection rate may be due to prior antimicrobial use frequent in developing countries. Antigen detection test by latex agglutination test or Immunochromatographic Test (ICT) for the detection of *S. pneumoniae* antigen is rapid, highly sensitive and not affected by prior antibiotic therapy.[94]

Pleural tuberculosis can be diagnosed by acid-fast stain microscopy of pleural fluid in only 18 to 23% of patients, but cultures of pleural fluid and histologic examination of pleural biopsy specimens permit the diagnosis in up to 95% of patients. Radiometric culture increases the speed of diagnosis in patients with pleural tuberculosis. Three other diagnostic tests are available to help establish the diagnosis of tuberculous pleural disease—tests for Adenosine Deaminase (ADA) and interferon-gamma and the polymerase chain reaction assay. In one study, pleural fluid ADA levels above 40 U/L were found in 99.6% of patients with tuberculous pleurisy.[95] Assay of interferon-gamma needs evaluation in developing countries where the disease is more prevalent. Two tests for *M. tuberculosis* nucleic acid are commercially available and nucleic acid amplification tests require rigorous standardization to prevent nonspecific results common with this technique.

Bacterial Lung Abscess

Microbiology

The predominant organisms responsible for lung abscess are bacteria, specifically mouth anaerobes that are normal flora in the gingival crevices.[96] Studies using rigorous sample collection techniques that avoid contamination with oral flora combined with reliable anaerobic culture methods have shown that anaerobes are found in about 90% of lung abscesses and are the only organisms present in about half of cases. The most frequently isolated anaerobes are *Peptostreptococcus spp*. (now probably identified as *Finegoldia magna*), *Fusobacterium nucleatum* and *Prevotella melaninogenica*.[97] Abscesses usually contain multiple anaerobe species, usually three to four per culture specimen; microaerophilic streptococci and viridans streptococci often are present as well.

Lung abscess occasionally may be caused by *S. aureus*, enteric gram-negative rods such as *Klebsiella spp*., *P. aeruginosa*, *Burkholderia pseudomallei* (melioidosis), *Pasteurella multocida*, GAS, *H. influenzae* types B and C, *Legionella spp*., *R. equi*, *Actinomyces spp*., and *Nocardia* spp. Oropharyngeal colonization with *P. aeruginosa,* other aerobic gram-negative rods and, less often, *S. aureus* is a common event in hospitalized patients, particularly patients who receive ventilatory support. These bacteria are important pathogens when lung abscess or necrotizing pneumonia develops during hospitalization and may produce infection as the sole pathogen or as one component of a mixed flora infection involving other aspirated oropharyngeal organisms. In patients with impaired cell-mediated immunity (AIDS, transplantation immunosuppression), opportunistic pathogens, such as mycobacteria, *Nocardia*, *Aspergillus*, and *Rhodococcus,* are important causes of cavitary lung lesions. In patients with impaired host defenses caused by granulocytopenia (leukemia, chemotherapy), aerobic bacteria (*P. aeruginosa*, *S. aureus*) and fungi, including *Aspergillus* and Zygomycetes, are important pathogens.

Diagnosis

Sputum Gram stains in these patients show many neutrophils and mixed flora, with many morphologically different bacteria; routine cultures usually grow normal respiratory flora. Because expectorated sputum is contaminated by oral flora containing large numbers of anaerobes, special techniques for obtaining lower tract specimens are necessary to confirm the role of anaerobes. These techniques include transtracheal aspiration, transthoracic aspiration, protected brush fiberoptic bronchoscopy, bronchoalveolar lavage with quantitative cultures,[98] and empyema fluid obtained by thoracentesis. Blood cultures rarely are positive in anaerobic lung abscess. Patients without the classic presentation and patients with secondary lung abscess should have stains and cultures of expectorated sputum for aerobic bacteria, mycobacteria, fungi, and, in some instances, parasites.

Systematic Approach to Interpretation of Plain Chest Radiographs*

D Behera

INTRODUCTION

In this chapter, various diagnostic methods used for the diagnosis of different lung diseases will be discussed. Important diagnostic tools include: Radiology, pulmonary function testing, bronchoscopy, bronchoalveolar lavage, thoracoscopy biopsy of various kinds, cytological methods and hematological investigations. Some of the microbiological and skin testings will be dealt with in chapters on specific diseases.

RADIOLOGY AND IMAGING

Chest Skiagram

Roentgenographic examination of the chest is an integral part in the diagnostic evaluation of all types of lung diseases. In fact, in the absence of a plain chest skiagram, workup of any lung disorder is not complete. While chest skiagram itself is not diagnostic of a particular disease, in correlation with clinical history, it provides important clues to the possible etiology and hints at whether any further diagnostic method is necessary or not.[1-11] After clinical examination, it is the first investigation of choice in any lung disease. Anatomical localization of pulmo-nary lesions is possible most of the time, and always an attempt should be made to collect this information. A lateral view is most often necessary for this purpose for recognizing various segments and lobes although posteroanterior views are good enough (Figs 24.1 to 24.7).

Posteroanterior (PA) View

The standard PA views are taken, when the X-rays pass through the body in a posteroanterior direction with the

patient facing the film cassette. The X-ray tube is placed at a distance of 6 feet. Although the standard technique is to use 60 to 80 kVp, many centers now use the high voltage technique using 120 to 350 kVp. The advantage with the latter technique is that the roentgenographic density of the bony thorax is reduced with an overall improvement in the quality of other structures, particularly the pulmonary vasculature and the mediastinum behind the heart. However, the disadvantage of this method is that the visibility of calcium is diminished. Proper positioning of the patient and the timing with

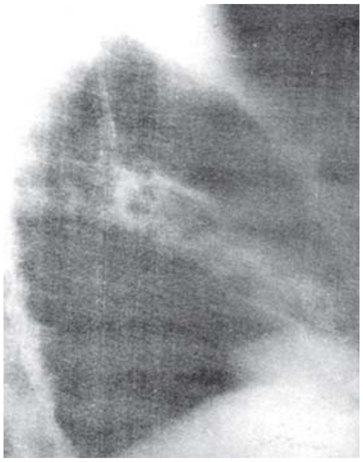

Fig. 24.6B: Cavity in the right middle lobe

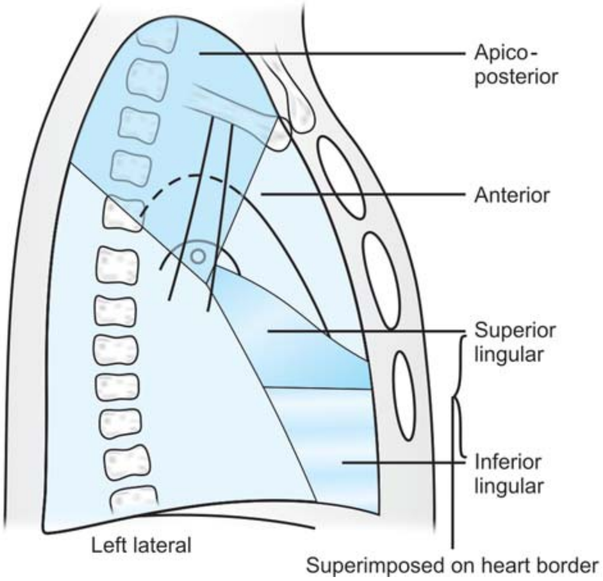

Fig. 24.7: Left lateral view of the chest skiagram showing segments of the left upper lobe including the lingular segments

phase of respiration (in full inspiration or TLC) is important for a better quality of PA film.

Anteroposterior (AP) View

This view of the chest radiograph is used when the patient is sick and cannot be moved into the radiology department—the so-called "portable X-rays". Such roentgenograms are technically inferior because of the patient's supine position, short focus-film distance and the inability in most patients to achieve a full inspiration. The mediastinal structures and the heart appear enlarged because the cassette lies at the back of the patient, and the heart is further away from the film and nearer to the X-ray tube.

Lateral View

These chest radiographs are particularly helpful in localizing a mediastinal or pulmonary lesion in its appropriate anatomical compartment. It differentiates a chest wall or cutaneous lesion from that in the lung. Small lesions in the retrocardiac or retrosternal areas or in the curvatures of the diaphragm hidden in the PA films are better seen in a lateral view. However, the lateral film is less easy to interpret than a PA film, as the two lungs and the mediastinum are superimposed one upon the other. The particular side to be X-rayed remains nearer to the film, i.e. in a left lateral view the left side is nearer to the film.[6,7]

Apicogram

Apicogram or the apical lordotic view is taken for the better visualization of the lung apices, which tend to be obscured on the standard PA projections by the upper ribs and the clavicles. The patient assumes a lordotic position arching the back, so that the nape of the neck rests on the top of the cassette, and the X-ray beam remains horizontal. The same view can be taken in an immobile patient in a modified technique. Superior mediastinum and the thoracic inlet can also be better delineated by this method. The minor fissure is better identified in the suspected cases of atelectasis of the right middle lobe in this view.

Oblique View

These skiagrams are infrequently used in respiratory workup. A standard anterior oblique view is obtained with the anterolateral wall of the chest placed against the cassette at an angle of about 45 degrees and the hands are held in extension above the head. Similarly the posterior oblique views are taken. These skiagrams are helpful in demonstrating pleural and pulmonary shadows close to the chest wall, pleural plaques in asbestosis and sometimes suspected rib pathology.

Lateral Decubitus Films

For this view, the patient lies on one side and the X-ray beam is oriented horizontally. The technique is particularly helpful in detecting small pleural effusions. Fluid collections as little as less than 100 ml can be detected by this method, whereas those taken in erect posture usually do not show pleural effusion of less than 300 ml. A more refined technique can detect fluid as little as 3 to 5 ml. The lateral decubitus view is also helpful to demonstrate the shifting of air fluid level in a cavity or to demonstrate a freely moving intracavitary loose body as a fungus ball or mycetoma in a tubercular cavity. Another usefulness of this roentgenography is to demonstrate air trapping, characteristic of endobronchial foreign bodies particularly in infants and young children.

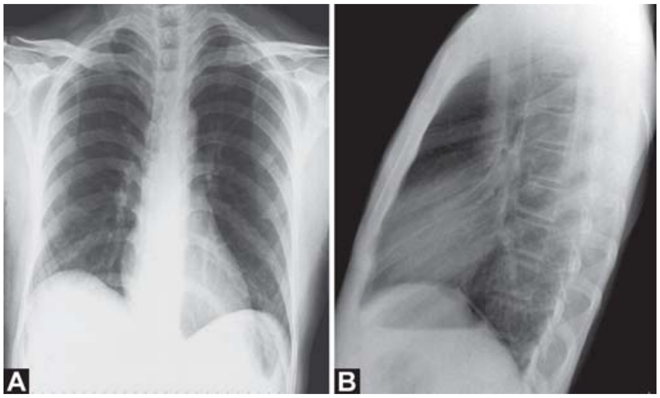
Expiratory Skiagrams

These are used (i) to investigate local or generalized air trapping; or (ii) to detect small pneumothoraces. When air trapping is generalized as in bronchial asthma or emphysema, there is little change in the lung density because of symmetrical diminution in the excursion of both diaphragms. However, localized air trapping (bronchial obstruction or lobar emphysema), the expiratory X-ray reveals restricted ipsilateral diaphragmatic elevation, a shift of the mediastinum to the contralateral side and a relative absence of the density change in the involved segment. In small pneumothoraces, when the visceral pleural line is not visible on the standard inspi-ratory films, an expiratory film may show the line more clearly. This is because of the volume of air in the pleural space being relatively greater in relation to the volume of the lung during expiration, which provides the better separation of the pleural surfaces, and the relationship of pleural line to the overlying ribs change during this maneuver.

Digital radiography is a recently introduced technique when the skiagram can be acquired digitally and can be stored like the data in a computer. The picture can be retrieved later. Further areas of particular interest can be studied more thoroughly.[11]

Fluoroscopy

Fluoroscopy or screening of the chest is helpful to visualize diaphragmatic excursions in cases of elevated diaphragms, and to distinguish a mass, particularly in the mediastinum whether it is pulsatile or not. In addition, this procedure is used more frequently now a days for transbronchial biopsy and percutaneous aspiration of lung or mediastinal masses for cytological examination. Loculated or deep-seated lung abscess, empyema or pleural effusions can be easily aspirated under fluoroscopic guidance. This is also used conveniently for other purposes like bronchography, pulmonary angiography and barium swallow examination of the esophagus.



Figs 24.8A and B: Normal chest X-ray

Reading a Chest X-ray

Normal X-ray

The reading of a standard PA film should proceed in a systematic manner so that no abnormality can be missed. It is always better to read such a film together with a radiologist, a practice most often very helpful. A suggested scheme of reading a chest X-ray is as follows:

First identify the quality and centering of the film. Neither an overpenetrated nor an under penetrated film is good (Figs 24.8A and B). One may then start looking at the extrapulmonary sites like the soft tissue shadows (Figs 24.9 to 24.11), including the breast shadows, skin and sub-cutaneous tissue thickness, bony cage, supraclavicular areas, scapulae and the areas below the diaphragms. The clavicles and ribs are to be looked for any abnormality (Figs 24.12A and B).

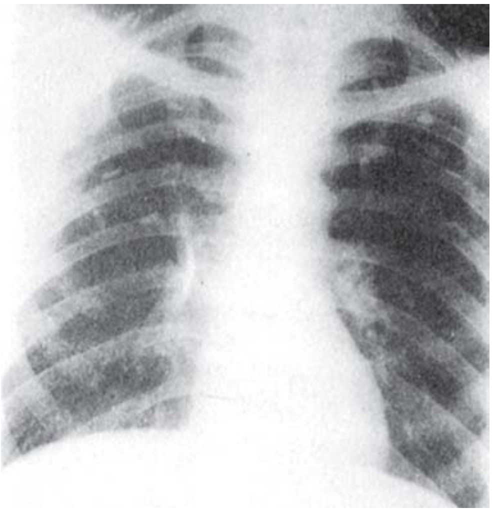

Fig. 24.10: Cysticerci in the soft tissue of the chest wall

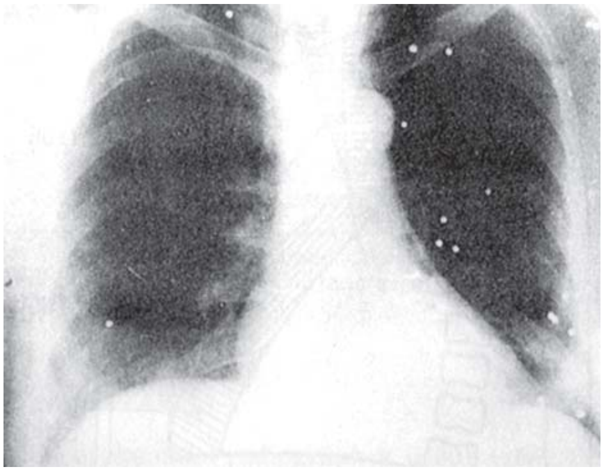

Fig. 24.11: Multiple bullets in the chest wall

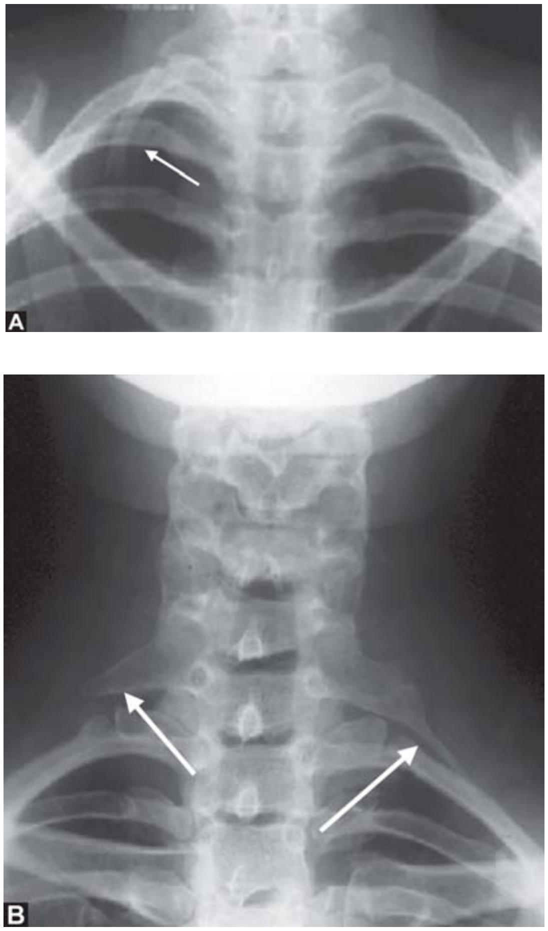

Figs 24.12A and B: Cervical ribs

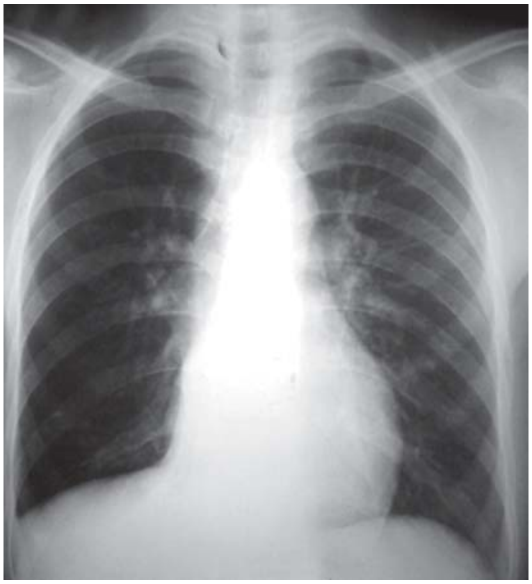

Fig. 24.13: CXR—Flattening of right dome of diaphragm—right subpulmonic effusion

The levels of both the diaphragms and their contour are to be studied and compared. Normally the right diaphragm is higher than the left and lies at the level of the sixth rib anteriorly (Figs 24.8 and 24.13).

The mediastinum is an important area, which is liable to be misread/over read. The tracheal and bronchial shadows can often be seen. The left pulmonary artery lies above the left main bronchus at the level of the seventh rib and is higher by one rib space than the right (at the level of eighth rib), which overlaps the right bronchus intermedius. The dimensions of both the arteries are to be measured. Normally, the maximum diameter is less than 17 mm. The aortic knuckle is a prominent structure on the left side. The cardiac size and its borders are then to be looked for. Normally, the right border of the heart does not extend beyond the spinal column. The Cardiothoracic Ratio (CT Ratio) is normally less than 50%. An attempt should always be made to look behind the heart, if necessary by taking a more penetrated or a left lateral view. Thus, any abnormality in the mediastinum can be picked up. The spine should always be examined carefully for any evidence of destruction, secondaries or cold abscess. Normally, the spine and the left lower lobe vessels are just visible through the heart shadow. The lung parenchyma is divided into three radiological zones. Upper zone is the area lying between the apex and the second intercostal space; the mid zone between the second and the fourth space; and the lower zone extends from the fourth space downwards. Any abnormality in each of these zones on either side should be noted very carefully.

Various deviations from the normal skiagram and few other abnormalities that can be seen are shown in Figures 24.14 to 24.34.

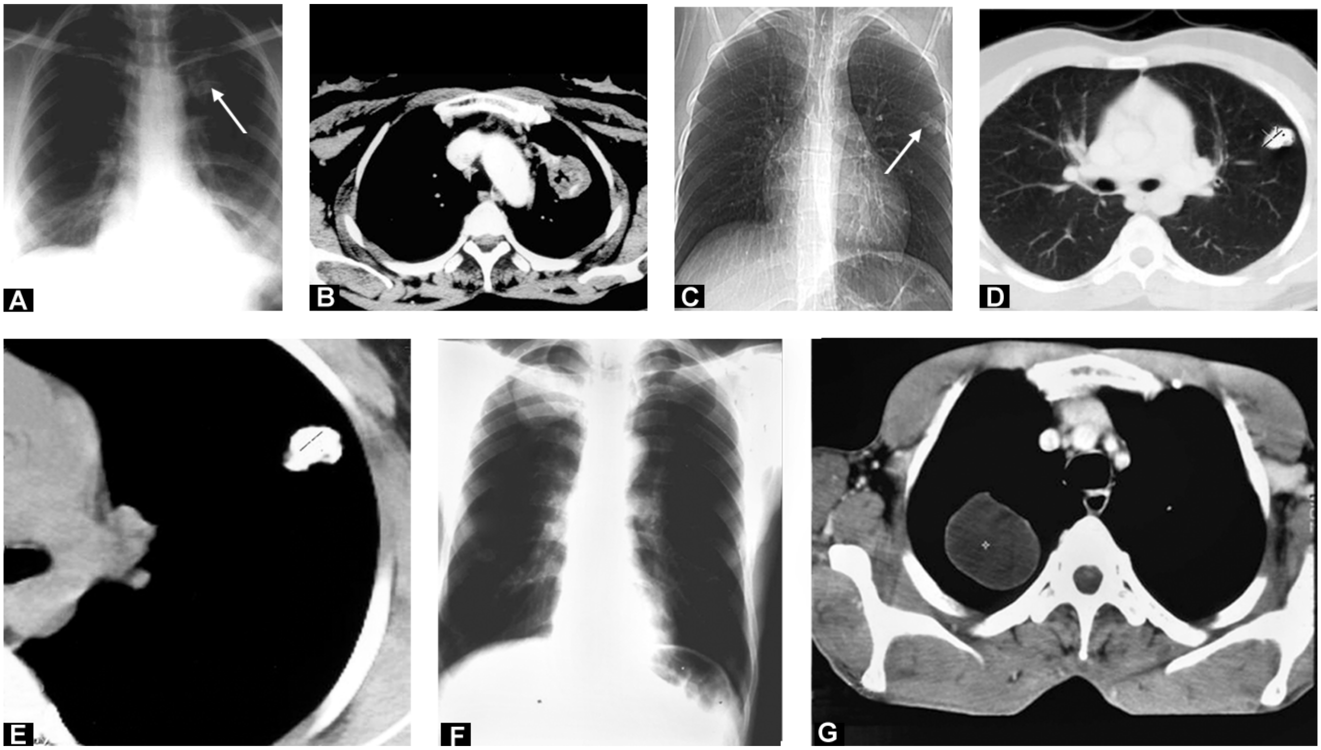
Limitations of Chest X-rays

Seven to twenty-one percent of normal chest X-rays reveal abnormalities on CT scan. Normal chest X-ray does not rule out mediastinal lymphadenopathy. Bronchiectasis, early interstitial lung disease, miliary shadows, nodules less than 5 mm may be missed on chest X-ray.

Abnormal Radiological Findings

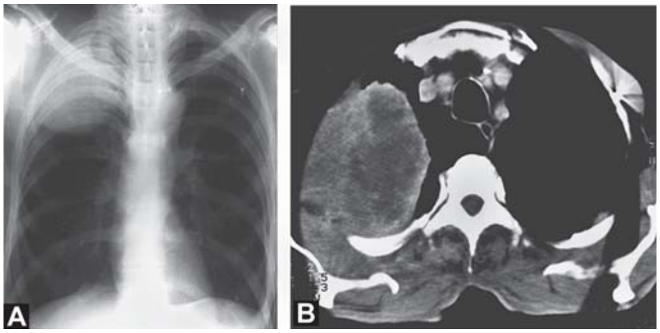
While it is not possible to describe all the radiological findings of all the pulmonary diseases, a generalized description of possible abnormalities in a chest skiagram will be discussed in brief. The findings may be divided into: (i) a solitary nodule; (ii) parenchymal shadows; (iii) hilar and mediastinal shadows and; (iv) abnormalities of the pleura.



Figs 24.35A to G: Solitary pulmonary nodule

Solitary Pulmonary Nodule (SPN) (Figs 24.35 and 24.36)

A solitary nodule[12] is defined as a shadow of either 4 cm or less in diameter with distinct borders and is surrounded by relatively normal lung parenchyma. When such a lesion is found in a chest skiagram, it is important to decide whether it is benign or malignant. Three points need special consideration: Age of the patient, doubling time, margins and calcifications if any. Solitary nodules in subjects below 40 years of age are relatively benign and in patients above the age of 40 years, carcinoma needs to be excluded particularly, if he is a smoker. All attempts should be made to obtain a previous skiagram, if one was taken, since a lesion lying for few years, is unlikely to be a malignant one. If the lesion in the present skiagram doubles in volume within seven days, it is more likely to be a benign one. However, secondaries from choriocarcinoma, testicular tumor and osteogenic sarcoma may grow very fast and for these a time limit of 11 days is suggested. On the other hand, lesions having a doubling time greater than 465 days are also benign. Anything outside these limits is more likely to be malignant. If the margins are lobular or nodular in appearance, the chances of malignancy are very high. A tail is suggestive of a granuloma or arteriovenous malformation. Small satellite lesions accompanying the nodule are common with tubercular lesions. Presence or absence of calcification in the nodule is another indicator of the benign or malignant nature of the lesion. While presence of calcification is taken as a sign of benign lesions, exceptions are there. Calcified nodules may be malignant in the following conditions. (a) a primary carcinoma engulfing a preexisting calcified granuloma; (b) solitary metastases from osteogenic sarcoma or chondrosarcoma; (c) primary



Figs 24.36A and B: Not solitary pulmonary nodule – not well-defined, invading the surrounding structure

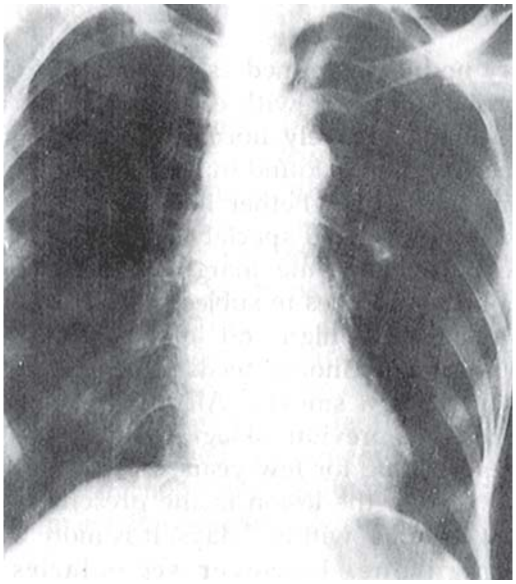


Fig. 24.37: Calcified solitary nodule on the left mid zone (tuberculoma)

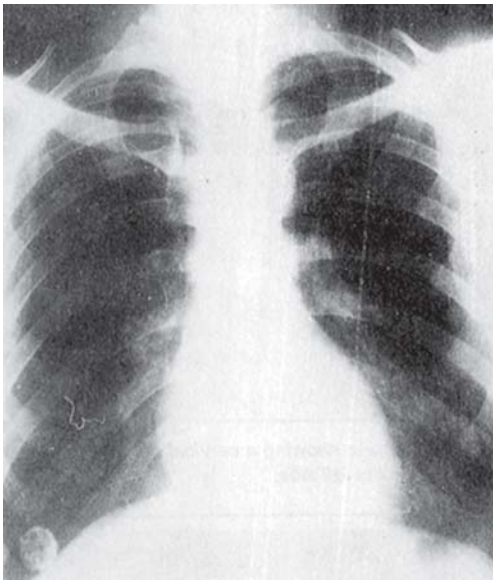

Fig. 24.38: Note popcorn calcifiction in a hamartoma in the right lower zone

peripheral squamous cell carcinoma or papillary adenocarcinoma (primary or metastatic); and (d) rare cases of carcinoid tumors or metastases from mucinous adenocarcinomas from colon. Benign lesions, which usually calcify, are: Tuberculoma, histoplasmoma or other fungal diseases (Fig. 24.37). The pattern of calcification is sometimes characteristic of certain lesions. A small central nidus is seen in granulomas or hamartomas; laminated appearance is almost pathognomonic of granulomas and indicates a benign nature of the disease; popcorn ball calcification is a characteristic feature of hamartomas (Fig. 24.38); and multiple punctate foci throughout the lesion may be seen either in a granuloma or hamartoma.

Other spherical lesions seen in a chest skiagram are due to: Carcinoids, cylindromas, leiomyomas, fibromas, neural tumors, tuberculomas, histoplasmomas, cryptococcomas, hydatid cyst, syphilitic gummas, lung abscess, progressive massive fibrosis, Caplan's syndrome, paraffin granulomas, aspiration pneumonias, rheumatoid nodules, Wegener's granulomatosis, bronchocentric granuloma, arteriovenous malformation, sequestration of lung, infarcts and interlobar effusion.

With the availability of different modern diagnostic techniques, assessment of solitary pulmonary nodule has become easier. But the problem is of high sensitivity of these methods. The main concern is the nature of the nodule—whether it is malignant or benign. Too sensitive methods will expose the patients for unnecessary exploration and many benign lesions will be resected unnecessarily. An SPN diagnostic approach that includes a transbronchial biopsy, then Percutaneous Needle Aspiration (PCNA), clinical observation, repeat CT scans, and repeat biopsies for continued suspicion of malignancy appears to reduce the unnecessary surgical excision of benign nodules from the current rate of 60% to 5% of SPN resections without affecting the survival of patients who have malignant SPNs. Both the ultrasound and radio-guided techniques are accurate to detect solitary pulmonary nodules, but the radio-guided method yields complications as compared with the ultrasound.[13] Ultrathin section with Multislice Computed Tomography (MSCT) and Multiplanar Reconstructions (MPR), Curved Multiplanar Reconstructions (CMPR) and Surface-Shaded Display (SSD) reconstruction can improve the demonstration of the patterns of tumor-bronchus relationships, which can reflect the pathological changes of the nodules to some extent and help differentiate malignant from benign tumors. According to one report CT demonstrated the relationship between the SPN and bronchi in 46 (86.8%) malignant and 18 (75.0%) benign nodules. Five types of tumor-bronchus relationships were identified with MSCT. Type I: The bronchus was obstructed abruptly by the SPN; type II: The bronchus penetrated into the SPN with tapered narrowing and interruption; type III: The bronchial lumen shown within the SPN was patent and intact; type IV: The bronchus ran around the periphery of the SPN with intact lumen; type V: The bronchus was displaced, compressed and narrowed by the SPN. Malignant nodules were most commonly of type I (58.5%), secondly of type IV (26.4%) and rarely of type V (1.9%). Benign nodules were most often of type V (36.0%), followed by type III (20.0%), type I (16.0%), and there were no type II. Types I, II and IV were more common in malignant nodules, whereas type V was seen more frequently in benign nodules ($p < 0.05$). There was no statistically significant difference between the two groups regarding type III.[14] Dynamic MR imaging and CT seem to be equally well suited for the differentiation between benign and malignant SPNs.[15]

Computer-Aided Diagnosis (CAD) has the potential to improve radiologists' diagnostic accuracy in distinguishing small benign nodules from malignant ones on High Resolution Computed Tomography (HRCT).[16] With a preoperative selection of the patients the rate of secondary thoracotomies due to bronchial carcinoma is low (4%). In patients with a previous history of malignant disease, 22% of the pulmonary lesions are benign. Video-Assisted Thoracoscopic Surgery (VATS) is a safe diagnostic method, with little discomfort for the patient.[17] Thoracoscopic resection of solitary pulmonary nodules is safely feasible. It results in better patient satisfaction, less nursing care and shorter in-hospital stay and the procedure can be performed without general anesthesia.[18] Ill-defined margins, spiculation, involvement of bronchi or vessels, and tumor enlargement visualized by CT are still important signs of malignancy even for nodules less than 10 mm in size. Tumor size, even for lung cancers measuring less than 10 mm, is not an indication for limited resection.[19] The use of MPR for CT-guided lung biopsy is useful for improving diagnostic accuracy with no significant increase in pneumothorax rate or total procedure time.[20] Recently, Dynamic MR imaging delineates significant kinetic and morphologic differences in vascularity and perfusion between malignant and benign solitary pulmonary nodules. Washout seems to be highly specific for malignancy. Malignant nodules show stronger enhancement with a higher maximum peak and a faster slope ($P < 001$). Significant washout (> 0.1% increase in signal intensity per second) is found only in malignant lesions (14 of 27 lesions). Sensitivity, specificity, and accuracy are 96%, 88% and 92 %, respectively, for maximum peak; 96%, 75% and 86% for slope; and 52%, 100%, and 75% for washout. When curve profiles and morphologic enhancement patterns are combined, sensitivity increases to 100%.[21]

Established methods (radiography for detection, spiral CT for characterization), after thorough evaluation, will soon be replaced by Magnetic Resonance Imaging (MRI). Recent experience with MRI points to its potential for the detection and characterization of pulmonary nodules while avoiding ionizing radiation. The development of indications for MRI of the lung (e.g. pediatric radiology) is not yet clear.[22] Pulmonologists are frequently asked to evaluate the CT-detected, small, noncalcified nodule invisible on standard chest radiography. Immediate biopsy is justified, if the likelihood of cancer is high, but if that likelihood is low or intermediate, a period of observation by CT is appropriate. VATS or thoracotomy are rarely necessary for a diagnosis of lung cancer in the CT-detected small pulmonary nodule.[23]

The challenge of diagnosis and management of solitary pulmonary nodules is among the most common yet most important areas of pulmonary medicine. Ideally, the goal of diagnosis and management is to promptly bring to surgery all patients with operable malignant nodules while avoiding unnecessary thoracotomy in patients with benign disease. Effective management of the solitary pulmonary nodule depends upon an understanding of decision analysis principles so that diverse technologies can be integrated into a systematic approach. In almost all patients, Computed Tomography (CT) is the best first step. Three key questions can then help to guide the workup of the SPN. These are what is the pretest probability of cancer, what is the risk of surgical complications, and does the appearance of the nodule on CT scan suggest a benign or malignant etiology. In patients with average surgical risk, Positron Emission Tomography (PET) scan is warranted when there is discordance between the pretest probability of cancer and the appearance of the nodule on CT scan. Thus, when either the patient has a low risk of cancer and the CT suggests a malignant origin, or when there is high risk of cancer and the CT appears benign, PET scan will be cost-effective. In most other situations, PET scanning is only marginally more effective than CT and fine needle aspiration strategies, but costs much more.[24]

Pulmonary hamartoma is the most common type of benign lung tumor. The vast majority of pulmonary hamartomas represent as solitary pulmonary nodules. Definite diagnosis and the treatment can be achieved by surgical resection with minimal morbidity. Tumor recurrence is very rare.[25]

Airspace Disease

Either liquid, or cells, or both replace the air within the acinus. Typically many contiguous acini are involved producing a homogenous opacity (Fig. 24.39). The size may vary from few centimeters to a whole lobe. Usual causes of such airspace opacities include: Alveolar edema, both cardiac and noncardiogenic, pneumonic

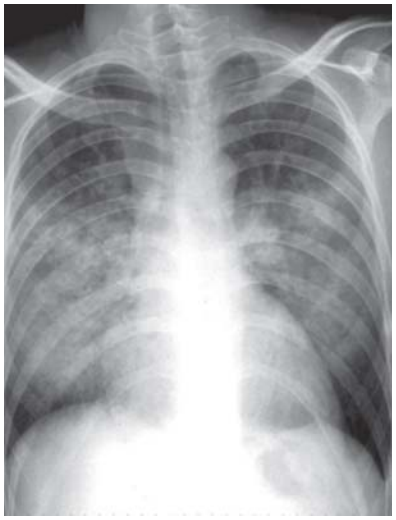

Fig. 24.39: Alveolar vs interstitial pathology

consolidations bleeding into the acinus; aspiration of blood or lipid; neoplastic infiltrations (bronchoalveolar cell carcinoma and lymphomas); alveolar proteinosis and early stages of fibrosing alveolitis. The classical findings of airspace disease include alveolar nodules or alveolar shadows, coalescence, poor margination, presence of airless bronchograms or bronchiolograms, air alveolograms, no or minimal atelectasis and the evolution is usually rapid. An alveolar shadow or the alveolar pattern of the shadow is nodular in shape measuring 4–10 mm in diameter with well-defined margins and there will be the presence of small multiple radiolucencies. Another characteristic feature of airspace consolidation is that it does not respect segmental or subsegmental boundaries as is usual with pneumococcal pneumonias or pulmonary edema. However, diseases produced by vascular route or through the tracheobronchial tree usually have a segmental distribution as in an-aspiration pneumonia. Air bronchogram commonly seen in a consolidation, is due to a patent bronchus containing the air column in the bronchi visible in the skiagram. The area of the lung should be completely airless for visualization of air bronchogram, as in collapse or consolidation (Figs 24.39 to 24.46).

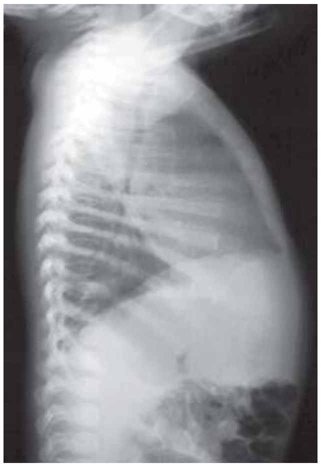

Fig. 24.44: Left upper lobe consolidation – Lateral view

Parenchymal Atelectasis

The basic difference between a consolidation and an atelectasis (collapse) is that while in the former the lung volume is maintained, in the latter, there is a volume loss (Figs 24.47 to 24.56). Common types of atelectasis described are: Resorption atelectasis and compression or passive atelectasis. A resorption atelectasis is mainly due to bronchial obstruction and consequent absorption of air from the alveoli distal to the obstruction rendering the alveoli airless. However, this type of atelectasis can occur without bronchial obstruction as in bronchiectasis. The only definite roentgenographic sign of this type of collapse is a loss of lung volume evidenced radiologically as the displacement of interlobar fissures. Other features are an increase in density locally, elevation of the ipsilateral hemidiaphragm, shift of the mediastinum to the side of collapse, compensatory overinflation, displacement of hilum, crowding of the ribs and absence

of air bronchogram. *Compression or relaxation* or *passive atelectasis* is seen with pneumothorax or pleural effusion. The lung is compressed medially. The compressed lung is greatly diminished in volume. Since the bronchi are usually patent unless there is an obstruction, air bronchogram is commonly present and should be looked for in all cases of pneumothorax and pleural effusion. Absence of this sign should raise the doubt of a proximal obstruction. *Rounded or helical atelectasis* is a recently described unusual radiological shadow. On conventional roentgenograph, the lesion is a fairly homogenous ill-defined pleural-based opacity, 6 to 7 cm in diameter, most commonly situated in the posterior portions of the lower lobes. The bronchovascular bundles in the vicinity of the mass are gathered together in a curvilinear fashion as they pass towards the mass simulating the tail of a comet

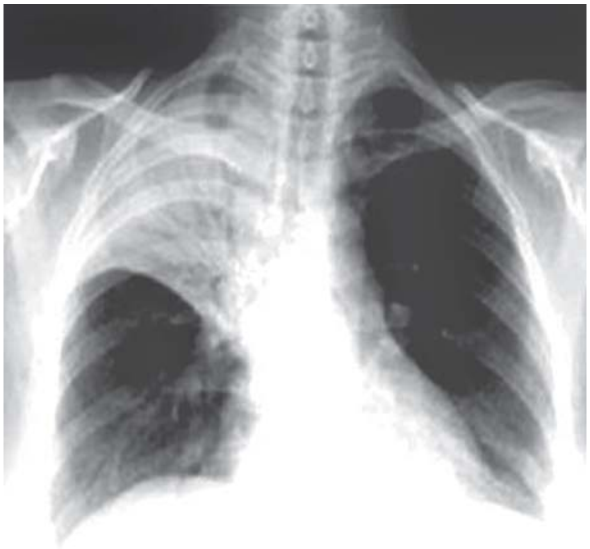

Fig. 24.55: Right upper lobe collapse

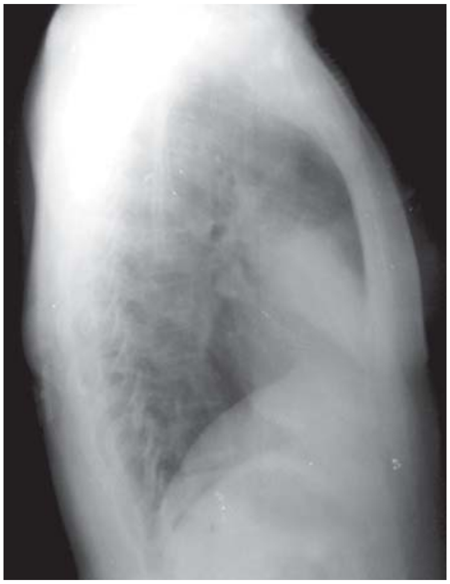

Fig. 24.56: Right middle lobe collapse. Note the shadow is bound by the two fissures which are also displaced

(Comet tail sign). The round opacity is due to a chronic inflammatory process in the parenchyma and most often confused with malignancy. The pathogenesis of this is due to pleural fibrosis, which contracts resulting in the compression of the nearby lung parenchyma.

Metastasis

Metastatic lesions to the lungs are common from many parts of the body because blood from all parts of the body comes to the lungs and because of the rich vascular supply in the lungs. Though typically, the metastatic lesions are rounded, multiple and more abundant in the lower lung fields, (Figs 24.57 to 24.59) many atypical forms can be seen. This can be in the form of lymphangitis carcinomatosis (linear streaky shadows) (Figs 24.60 and 24.61) cannonball lesions and cavitating lesions. Pulmonary metastases typically present as mostly multiple and bilateral, well-defined, noncalcified pulmonary nodules with predominantly basal and peripheral location. Ill-defined, cavitating, calcified and endobronchial metastases are uncommon. In the absence of pathognomonic findings precise differentiation from other even benign pulmonary nodules is almost impossible. Demonstration of contrast enhancement at CT or MRI or evidence of growth at serial examinations supports the diagnosis of pulmonary metastases. In uncertain cases percutaneous fine-needle aspiration or cutting needle biopsy will allow diagnosis with the acceptable risk of complications and patient discomfort. The only relatively common complication of pneumothorax can and should be controlled by the interventional radiologist by aspiration or drainage.[26]

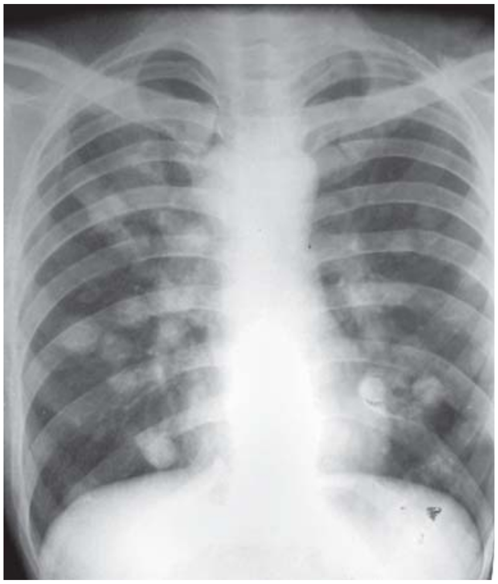

Fig. 24.57: Canonball metastasis

Fibrosis

Parenchymal fibrosis has the same findings as in a resorption collapse except that it is a more chronic process and the opacity is not uniform. Signs of chronicity in the

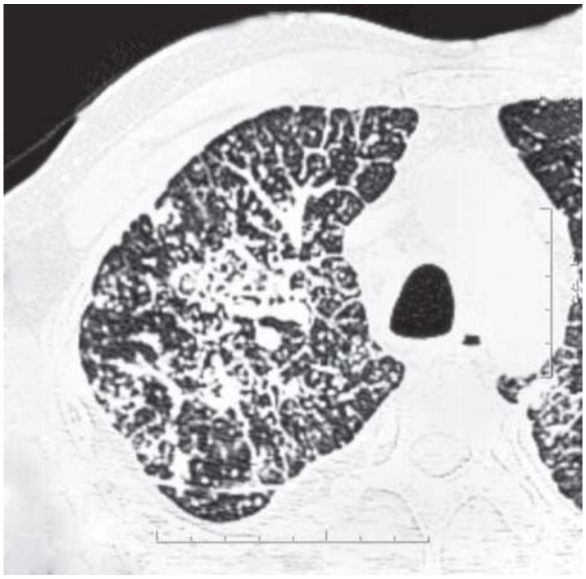

Fig. 24.61: CT picture of lymphangitis carcinomatosis

form of rib crowding and alterations of the thoracic shape may be there. Associated cavity may be seen, as the common cause of fibrosis is tuberculosis (Fig. 24.62).

Interstitial Disease

Four radiological patterns have been described, (a) Reticular pattern (Fig. 24.63): These are a network of curvilinear opacities surrounding spaces of air density and are due to the thickening of the interstitium due to an increase in the total amount of tissue. It may be fine, medium or coarse. Fine reticulation is a prominence of interstitial shadows. Coarse reticulation is characterized by large cystic spaces, 1 cm or more in diameter ringed by soft tissue shadows. Medium reticulation lies between these two extremities and is characterized by 3 to 10 mm cystic spaces. Honeycombing or honeycomb pattern denotes cystic spaces in the range of medium and coarse reticulation. (b) Nodular pattern: A nodular pattern is produced when spherical lesions accumulate within the interstitium. Interstitial nodules differ from airspace nodules in that these are homogenous, well circum-

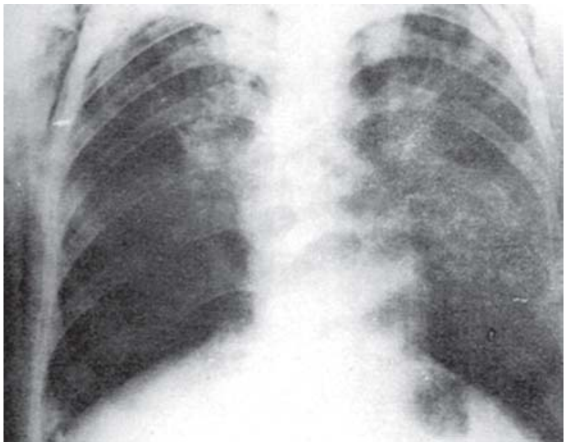

Fig. 24.62: Fibrosis with cavities in both upper zones because of pulmonary tuberculosis. Note the subcutaneous emphysema. Rounded hyperluscent areas overlying heart and mediastinum are due to air in the tissue plane

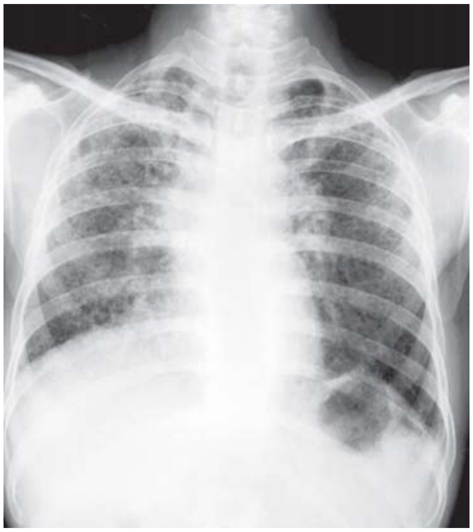

Fig. 24.64: Reticulonodular shadows

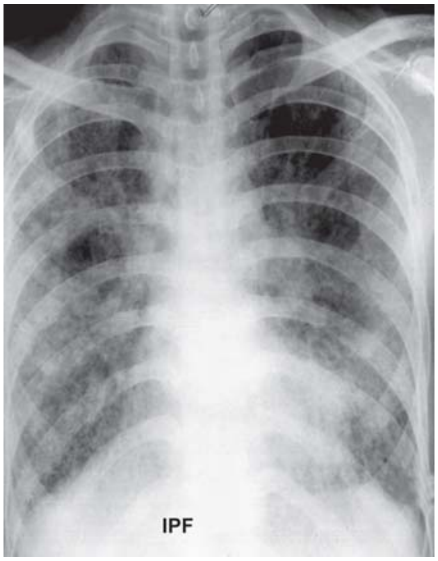

Fig. 24.63: Interstitial pathology

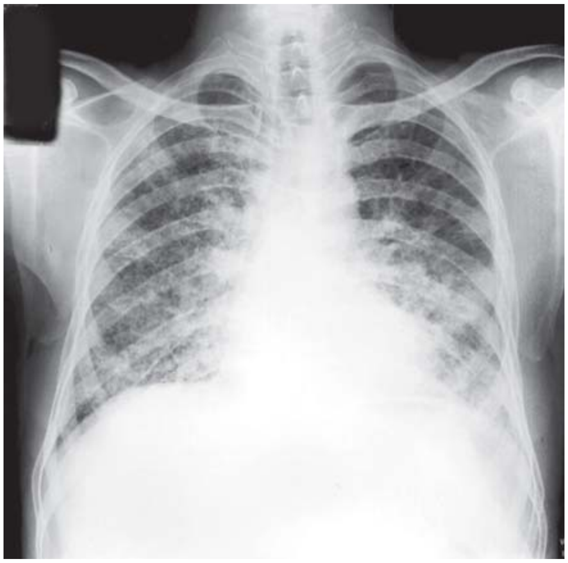

Fig. 24.65: Lymphangitis carcinomatosis

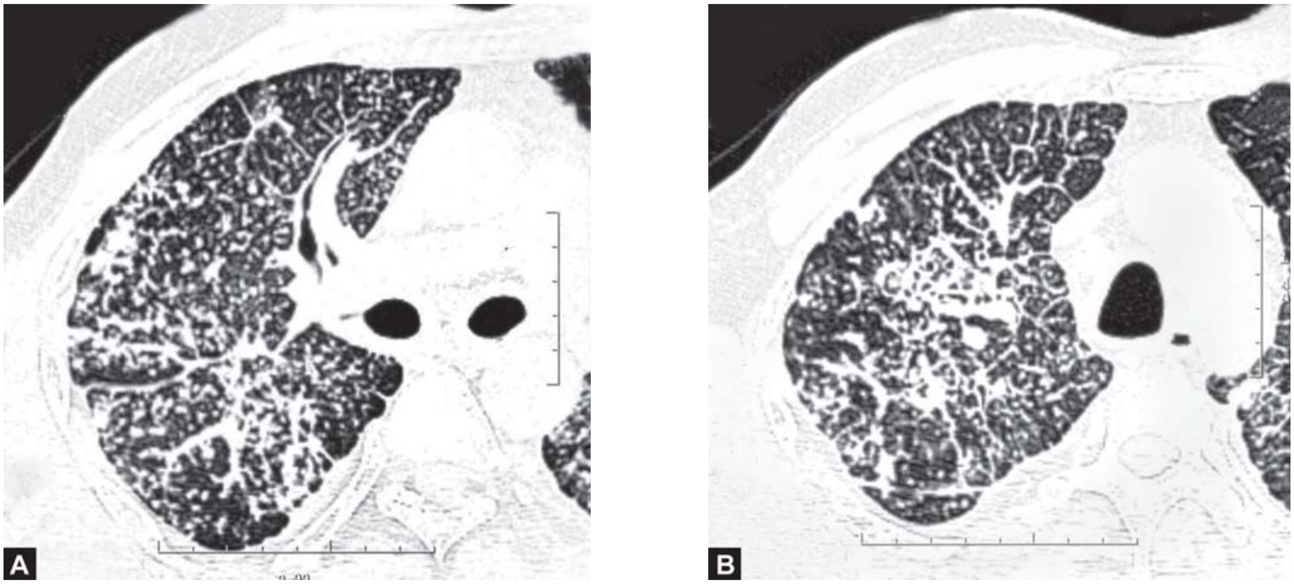
scribed and are of variable size. Such nodular diseases are common in miliary tuberculosis, early disseminated hematogenous carcinomatosis, silicosis and sarcoidosis. (c) Reticulonodular pattern (Fig. 24.64): When both the reticular and nodular patterns are seen in the X-ray, it is called as a reticulonodular pattern. This is commonly seen in sarcoidosis and interstitial pneumonitis. (d) Linear pattern: This pattern is due to thickening in or around the bronchoarterial bundle, perivenous interstitium or interlobular septa (Kerley A and B lines). Besides early pulmonary edema, lymphangitis carcinomatosis produces these types of shadows (Figs 24.65 and 24.66).

Miscellaneous Radiological Features

The smoothness of contour of a shadow in general suggests a benign nature of the lesion, whereas nodularity or lobulation indicates malignancy. "Satellite lesions" are small punctate opacities in close proximity to a larger



Figs 24.66A and B: CT picture of lymphangitis carcinomatosis

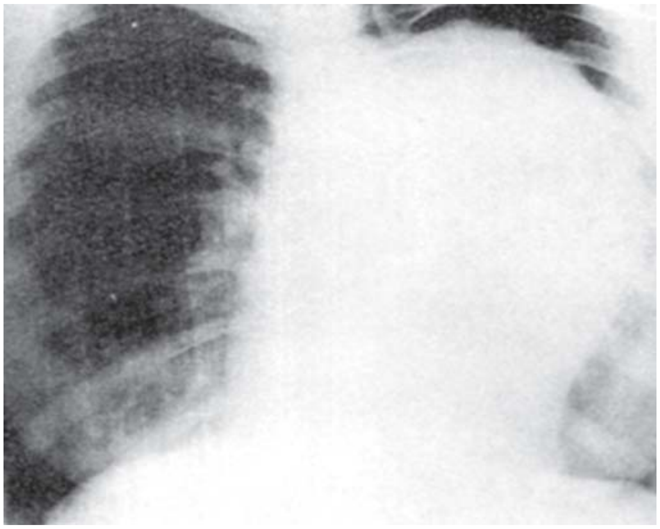


Fig. 24.67: Mediastinal mass. Note the medial border is merged with mediastinum

lesion, usually a solitary pulmonary nodule, and are thought to suggest an inflammatory nature of the lesion and are most common in tuberculosis.

The contour and margin of an opacity are important to decide whether it is a mediastinal, intrapulmonary or extrapulmonary mass. If the medial border is contiguous with the mediastinum and the mediastinal margin cannot be distinguished, it is usually a mediastinal mass (Fig. 24.67).

A mass that originates within the pleural space or extrapleurally, displaces the pleura and the underlying lung inwards such that the angle formed by the margins of the mass and the chest wall is obtuse. By contrast, an intrapulmonary mass tends to relate to contiguous pleura with an acute angle. This is called the "extrapleural sign" (Figs 24.68A and B). Occasionally there are exceptions to this rule.

Position of the interlobar fissures provides important clues to the underlying pathology (Figs 24.69 to 24.71). As mentioned earlier, displacement of the fissure towards a zone of opacity indicates volume loss and usual with atelectasis. Displacement to the opposite direction and bulging of fissure indicates an increase in the volume of the lobe and is a characteristic feature of *Klebsiella pneumonia*. Rarely Staphylococcal pneumonia, *Yersinia pneumonia*, acute lung abscess and space occupying lesions produce this bulging of the fissure. Transgression of the fissure is very uncommon in many lung diseases as the fissure behaves as a barrier; however, such transgression is not uncommon in fungal infections and in actinomycosis.

Cavity

A cavity is a gas containing space with a wall thickness of greater than 1 mm (Figs 24.72 to 24.75). An abscess is a

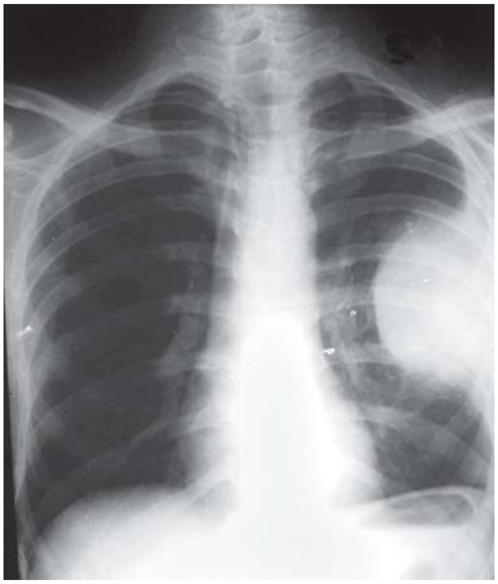

Fig. 24.68A: Extrapulmonary sign—A case of pleural tumor

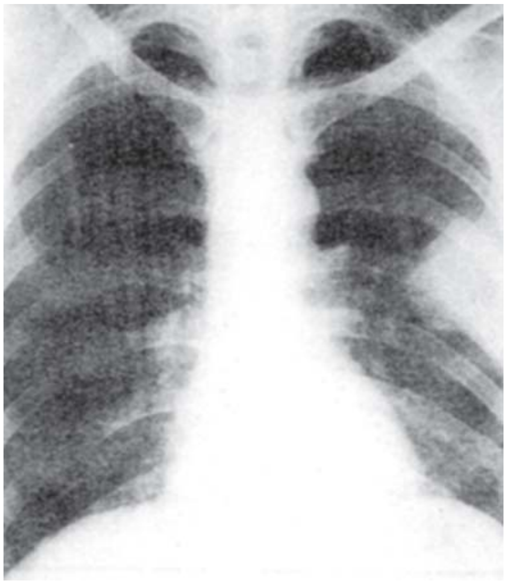

Fig. 24.68B: Extrapleural sign. Note the obtuse angle the shadow produces

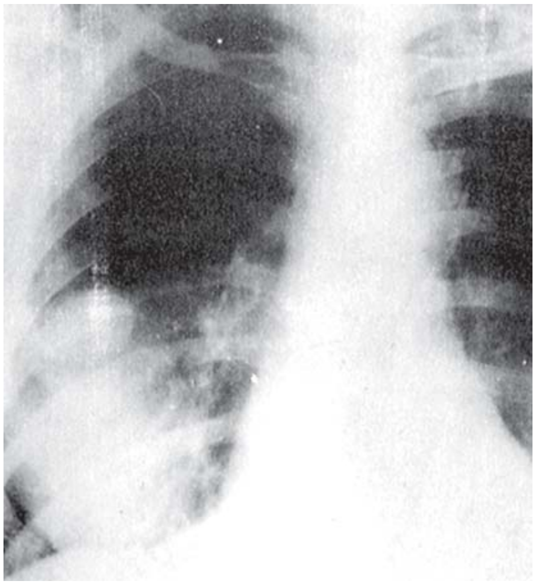

Fig. 24.69: Two homogenous opacities in the right mid and lower zones. The shadows are confused with secondaries or cysts. Lateral chest skiagram (*see* Fig. 24.70) reveals the true diagnosis

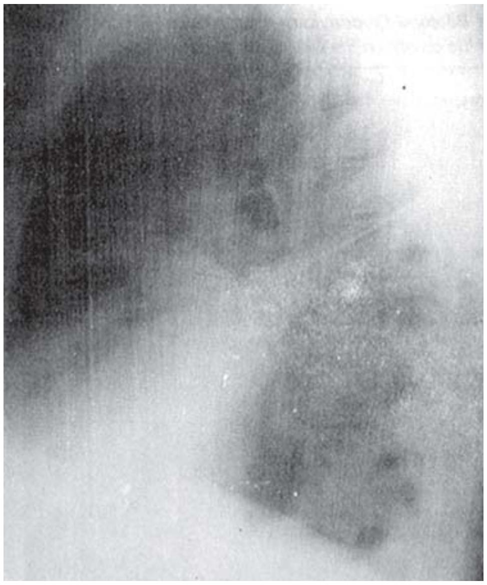

Fig. 24.70: Pleural effusion (encysted) in the oblique (major) and horizontal (minor) fissures

cavity containing fluid. It may even be solid when there is no necrosis or communication with the bronchial tree. In any cavity, the wall, regularity of its inner lining, contents, and the number should be noted. The cavity wall is usually thick in acute lung abscess, primary and secondary carcinomas, and Wegener's granulomatosis. The wall is thin in infected bullae, posttraumatic cysts and INH cavities (Fig. 24.76). It is observed that all lesions in which the thickest part of the cavitary wall is 1 mm, are benign; when 4 mm or less, 92% are benign; between

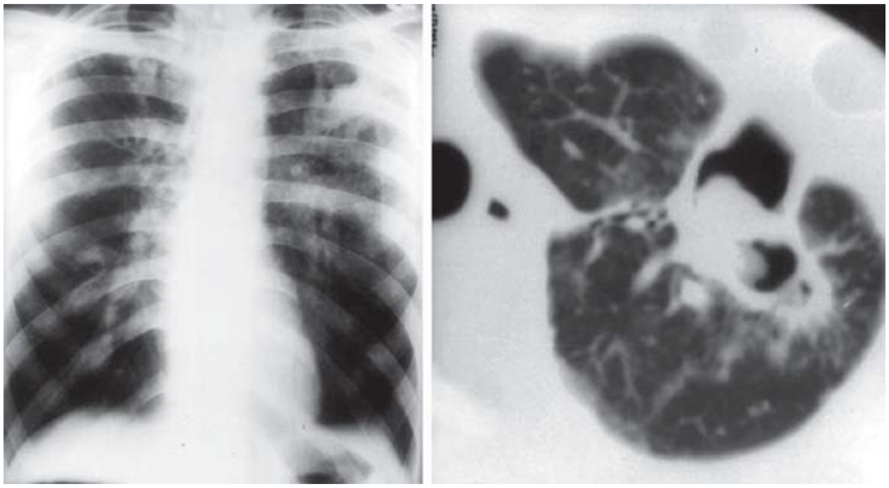

Fig. 24.74: Pulmonary cavitation

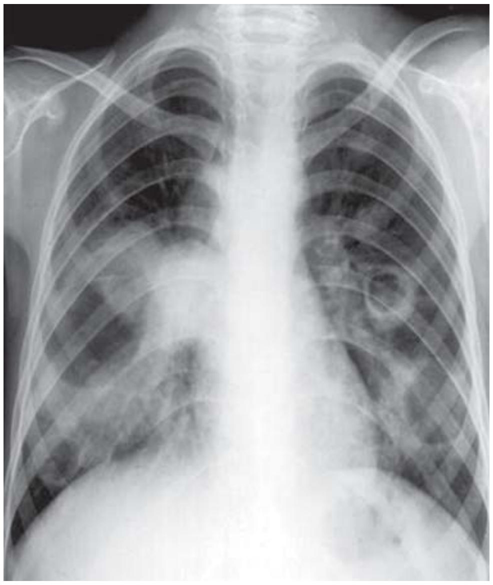

Fig. 24.75: Multiple cavitation

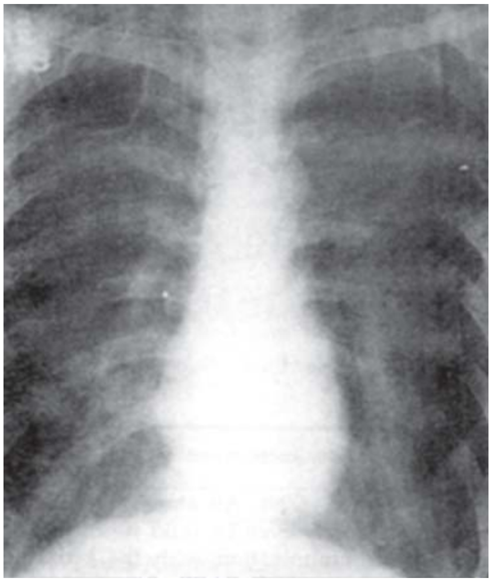

Fig. 24.76: Thin walled INH cavities in the upper zones

5–15 mm the chances of benign and malignant are equal; and when greater than 15 mm, 92% chance is that the lesion is malignant. It is important to measure at the thickest part of the wall. The inner lining is irregular and nodular in malignant cavities (Fig. 24.77), shaggy in acute lung abscess and smooth in most other cavitary diseases. The content of the cavity is mostly liquid (pus) in infective conditions. A fungus ball or blood clots in a cavity may give rise to a crescent around the mass and they change their position (Fig. 24.78). The collapsed membrane of a ruptured hydatid cyst float on top of the fluid within the cyst giving rise to the "water lily sign" (Fig. 24.79). Pulmonary gangrene may also be present as a floating mass inside a cavity, seen sometimes in *Klebsiella pneumonia*. A solitary cavity is usually seen in acute lung abscess (Fig. 24.80), primary cavitary carcinoma and posttraumatic cavities. Multiple cavities are, seen in cavitating secondaries, Wegener's granulomatosis and acute pyemic abscesses secondary to bacterial endocarditis and other septicemia.

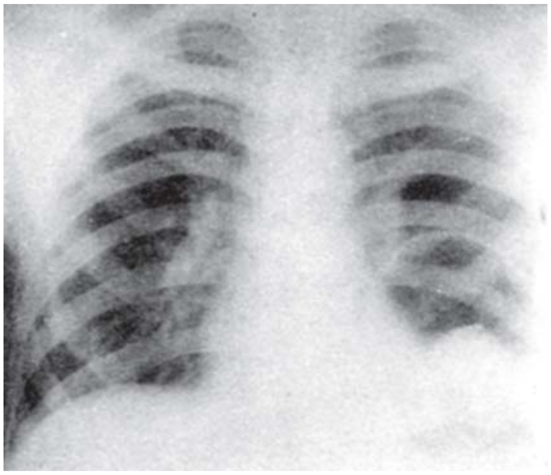

Fig. 24.79: Hydatid cyst in the left lower lobe. Note the "water-lily" sign

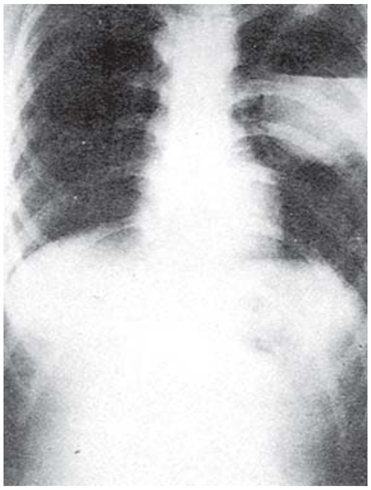

Fig. 24.80: Lung abscess in the left upper lobe

Bullae or Cyst

These are air containing spaces more than 1 cm in diameter and less than 1 mm wall thickness (Fig. 24.81). Bulla is associated with emphysema (Fig. 24.82). Acute staphylococcal infections in children produce multiple cystic lesions called pneumatoceles due to a check valve type of obstruction of bronchioles and necrosis of the lung parenchyma. Other diseases producing bullae or cysts are: Bullous emphysema, cystic bronchiectasis, bronchopulmonary dysplasia and Wilson-Mikity syndrome, cystic adenoid malformation of the lung, staphylococcal and Gram-negative pneumonia, necrobiotic nodule of rheumatoid arthritis and traumatic lung cysts.

Calcification

It is an important radiological sign and should always be looked for. Most commonly they are of dystrophic type (calcification in dead or damaged tissue) and less

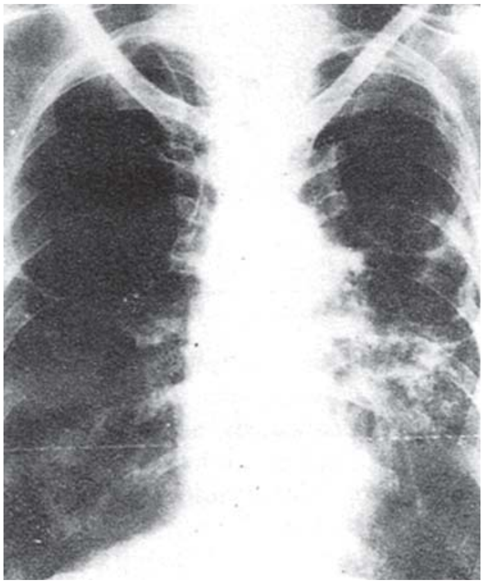

Fig. 24.81: Thin walled cysts in both upper zones

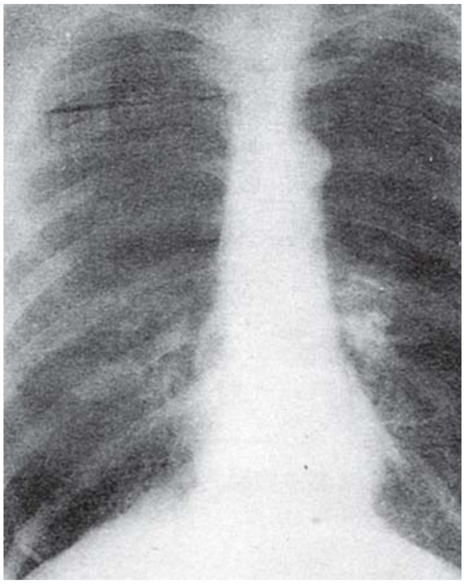

Fig. 24.82: Bullae seen on both upper lobes in a case of emphysema

commonly they are metastatic in nature (calcification of living tissue) as in hypercalcemia. Calcification may be either (a) pulmonary (b) pleural (c) lymph nodal or (d) mediastinal.

Pulmonary: Single calcifications are more common than multiple diffuse areas of calcification. Usual causes of a densely calcified focus are healed granulomatous lesions (Fig. 24.83) like tuberculosis, histoplasmosis, coccidioidomycosis and blastomycosis. Calcification in solitary pulmonary nodules has been discussed earlier. Diffuse patchy calcification (Fig. 24.84) is seen in healed disseminated tuberculosis, alveolar microlithiasis (typically tiny punctate calcispherites), silicosis (multiple nodular calcification or ossification), mitral stenosis (larger sized; greater than 8 mm in size, may even ossify), disseminated histoplasmosis and varicella pneumonia. Intensive

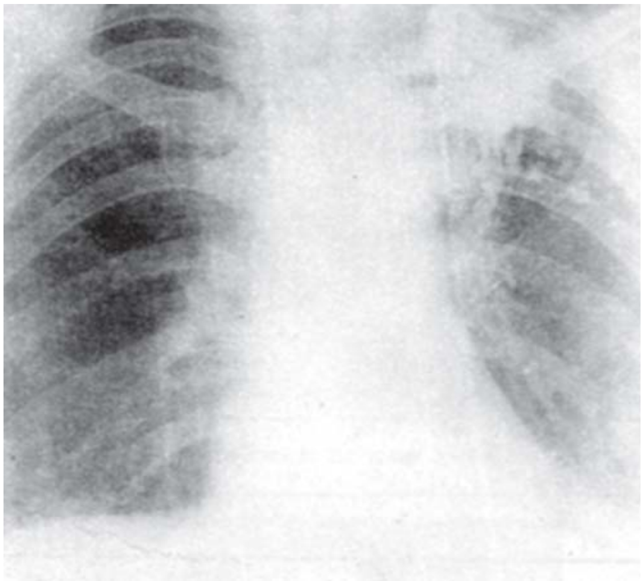

Fig. 24.83: Dense calcification in left upper zone after healed tuberculosis

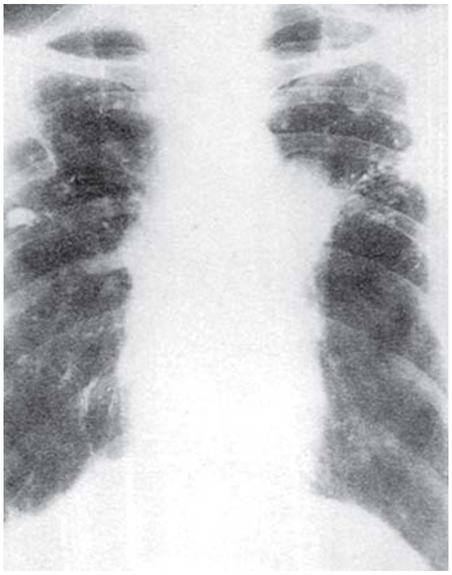

Fig. 24.84: Discrete parenchymal calcification following pulmonary tuberculosis

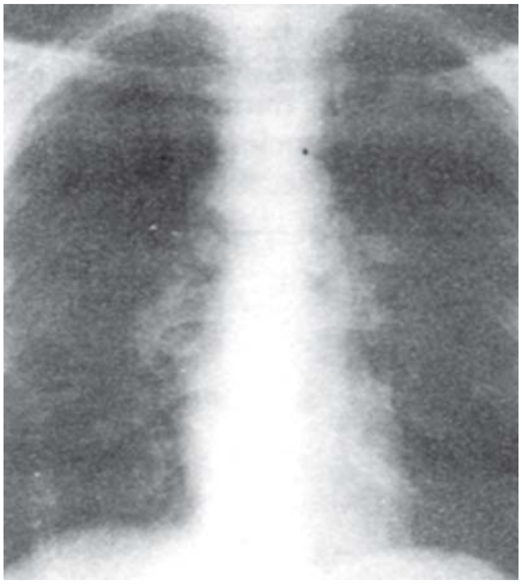

Fig. 24.85: Lymph node calcification in both hilar areas

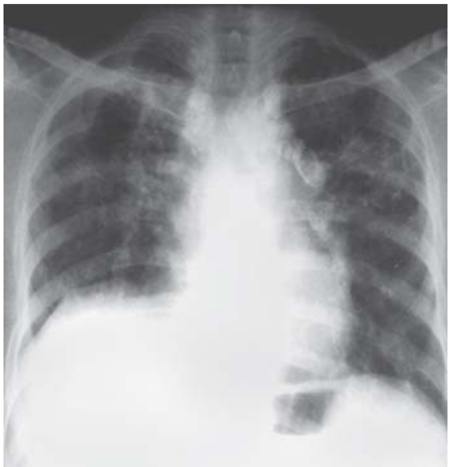

Fig. 24.86: “Eggshell” calcification in a case of silicosis

ossification of the pulmonary tissue is rare and may occur in fibrosing alveolitis, following Busulfan therapy and it may be idiopathic. Metastatic calcification can occur in long-standing hypercalcemia due to secondary hyperparathyroidism as in chronic renal failure and specifically in those who are maintained on hemodialysis. Other causes can be diffuse myelomatosis and in conditions of elevated serum calcium and phosphorus. Metastatic type of calcification has a predilection for the apical and subapical zones.

Lymph node calcification: The calcification in the lymph nodes is irregularly distributed throughout the node and the usual causes include healed tuberculosis, and histoplasmosis (Fig. 24.85). Eggshell type of calcification is uncommon and typically is a ring of calcium at the periphery of the lymph node (Fig. 24.86). Silicosis and coal workers pneumoconiosis are the usual causes. Rarely, sarcoidosis, irradiation of the lymph nodes particularly due to Hodgkin’s disease, blastomycosis, histoplasmosis, progressive systemic sclerosis and amyloidosis can produce this type of calcification.

Pleural calcification (Figs 24.87 to 24.89)*:* The common causes of this type of calcification are: Hemothorax, pyothorax, tubercular empyema and all other causes associated with a thickened pleura and fibrothorax (Fig. 24.90). They may form a broad, continuous sheet or multiple discrete plaques. The calcification usually extends from about the level of the midthorax posteriorly around the lateral lung margin going inferiorly and roughly runs parallel to the major fissures. Calcification

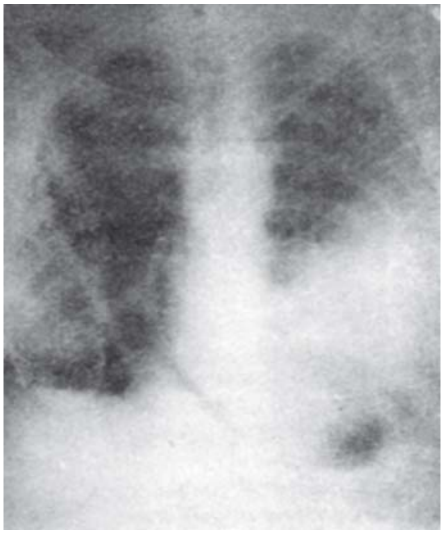

Fig. 24.87: Sheet-like calcification in the right pleura. An encysted empyema is seen on the left side

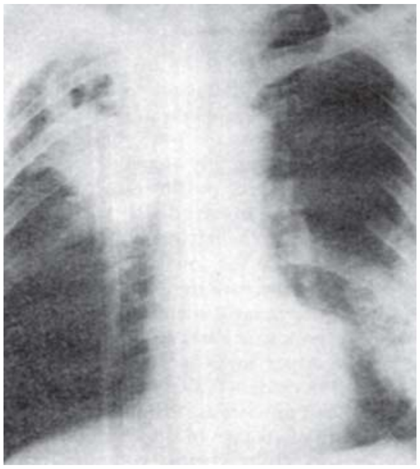

Fig. 24.88: Pleural calcification (left) with a cavitating carcinoma on the right side

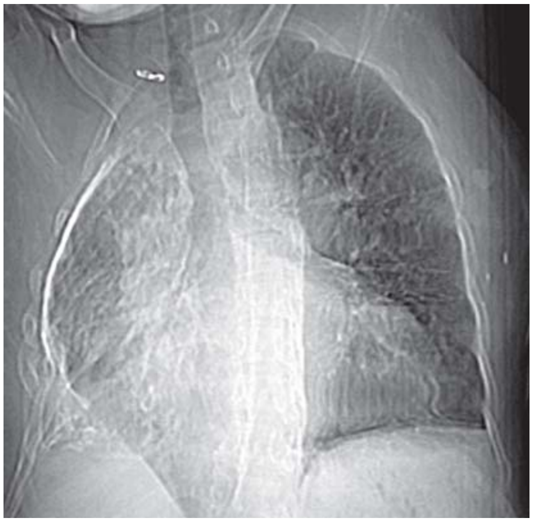

Fig. 24.89: CXR—Dense right pleural calcification

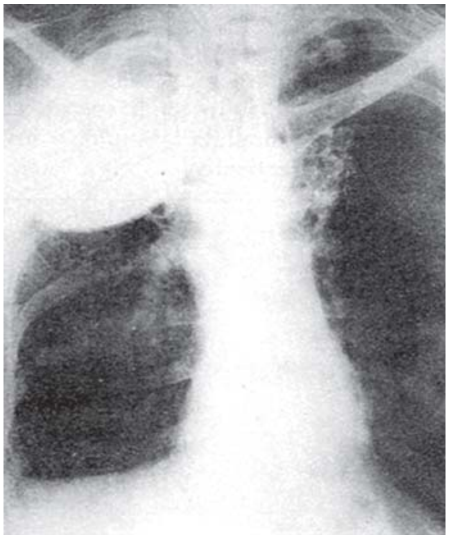

Fig. 24.90: Calcification in an encysted empyema. Note hilar calcification on left side

may be on the inner surface of the thickened visceral or parietal pleura. Other causes of pleural calcification include silicatoses (asbestosis and talcosis). Calcification in asbestosis is characteristically present as bilateral plaques involving the parietal pleura with extensive thickening. It is rarely associated with pulmonary fibrosis or carcinoma, the two other complications of asbestos exposure. The exposure to asbestos for such calcification may be very short and mechanical irritation is the probable underlying mechanism of pleural calcification of asbestosis.

Other rare sites of calcification may be the cartilages of trachea, bronchi and is common in elderly women. Tracheobronchopathica osteochondroplastica is a rare condition where nodules or spicules of cartilages and bones are formed in the submucosa of trachea and bronchi and is associated with chronic airflow limitation. The pulmonary arteries can rarely be calcified.

Anatomic Distribution

Certain lesions have characteristic anatomic distribution. Aspiration pneumonia is gravity dependent and in the supine position, the posterior segments of the upper lobes are commonly affected than the anterior segments. In the erect posture, lower lobes are the common sites to be involved. The right lung is most often involved than the left one. Pulmonary infarction is more common in the lower lobes than the upper lobes because of the pattern of blood flow being more to the former. Similarly metastatic lesions are more common in the lower lobes (Fig. 24.91) and a solitary mass in the upper lobes is rarely metastatic. However, in a bedridden patient the upper lobe is the common site of metastasis. Primary and cavitary carcinomas are more often seen in upper lobes. Postprimary tuberculosis in adults is more common in the apical and posterior segments of the upper lobes and superior segments of the lower lobes possibly because of a high ventilation-perfusion ratio and high PO_2 in the

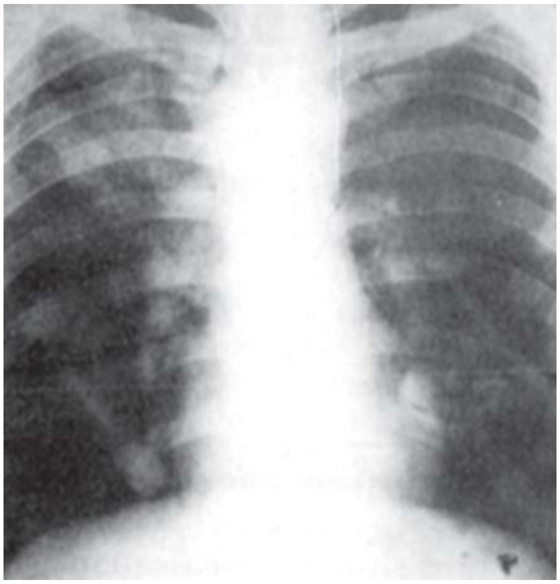

Fig. 24.91: Cannonball secondaries in the lungs from a testicular seminoma

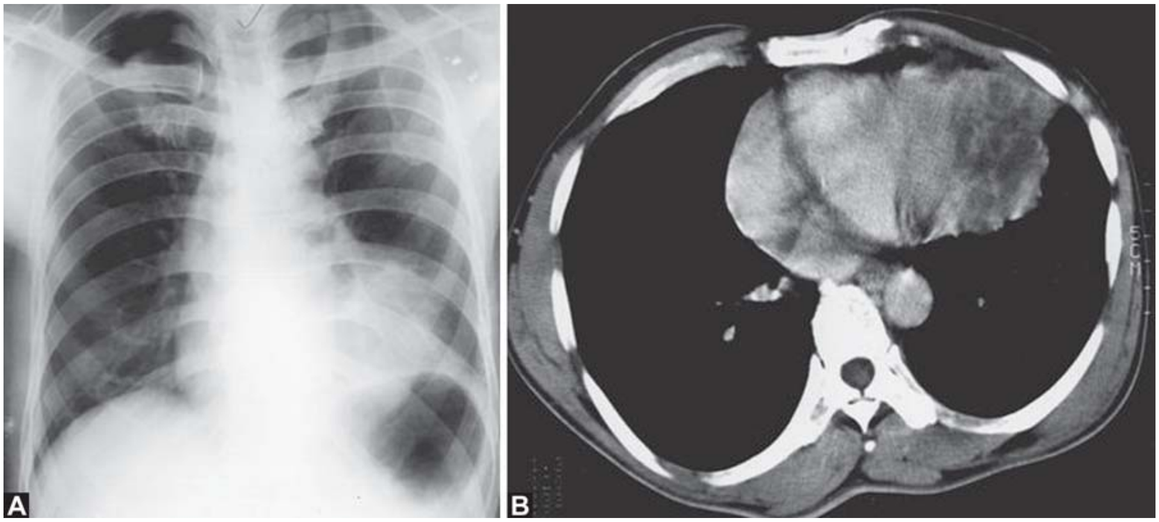
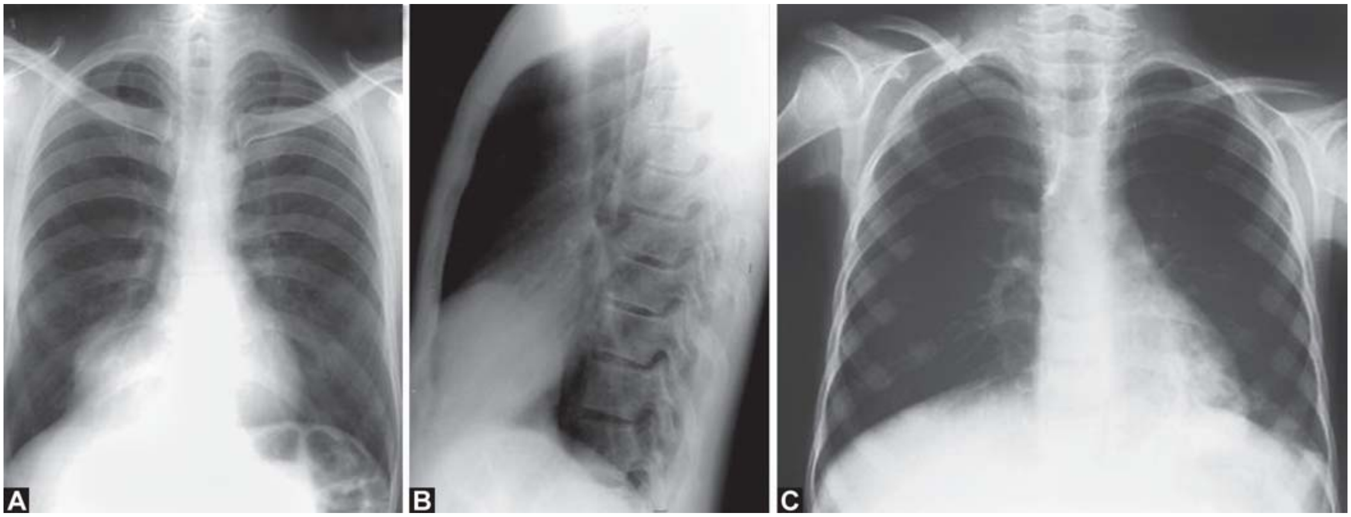


Figs 24.92A and B: Note obliteration of left cardiac border and part of diaphragm

upper lobes. Tuberculosis is rare in lateral lung zones. However, it must be remembered that this may not be true always. Primary tuberculosis commonly involves the anterior segments of the right upper lobe and middle lobe. Radiological changes in interstitial fibrosis are more evident in the lower lobes. Silicosis, sarcoidosis and eosinophilic granuloma involve the upper lobes more frequently.

Silhouette Sign

This is another important radiological sign (Figs 24.92 to 24.94) helpful to localize the lesion in the lungs. Although anatomical localization of most pulmonary lesions is possible in most cases from a PA and lateral views, it may not be possible when there are multiple segments of both lungs involved and when only an AP view is available for study. In these circumstances Silhouette sign is very helpful. Normally, the mediastinum and the diaphragm are radiologically visible because of the contrast with the contiguous air containing lungs. However, when opacity is situated in any position of the lung adjacent to the mediastinal or diaphragmatic border, that border is obliterated and can no longer be distinguished roentgenographically. Accordingly, an opacity within the lungs that does not obliterate the mediastinal or diaphragmatic contour cannot be situated within the lung contiguous to these structures. The sign is helpful in distinguishing right middle lobe and lingular segments on the left from the lower lobes, which will obliterate the



Figs 24.93A to C: Silhouette sign

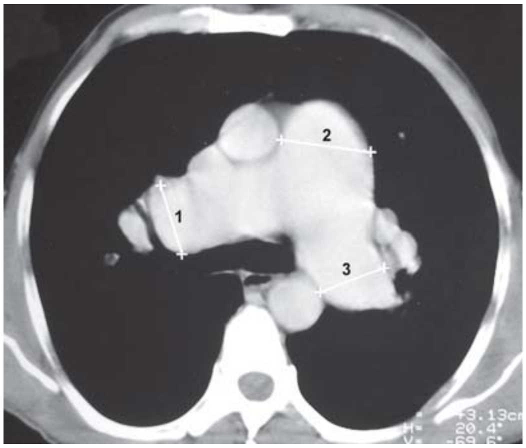

Fig. 24.97: Pulmonary hypertension

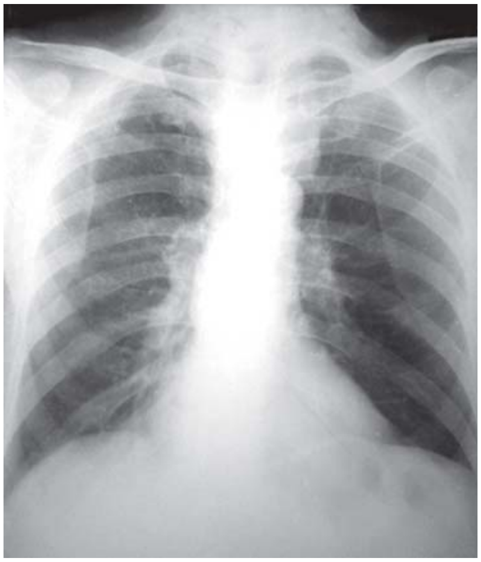

Fig. 24.98: Right paratracheal lymph node

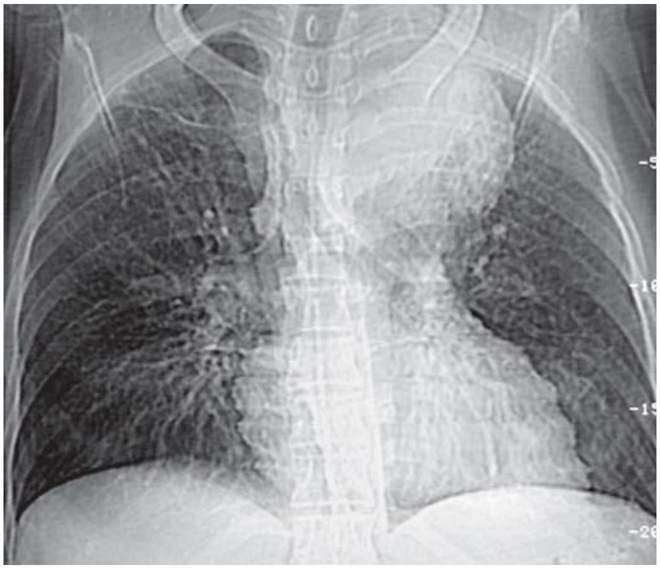

Fig. 24.99: CXR—Left paratracheal mass: Castleman disease

right and left cardiac borders respectively. Similarly obliteration of the aortic knuckle indicates involvement of the posterior segment of the left upper lobe; obliteration of the ascending aorta and superior vena cava indicates involvement of the anterior segment of the right upper lobe and the posterior paraspinal gutter is obliterated by opacities in the left posterior gutter.

Mediastinal and Hilar Shadows

All suspected mediastinal and hilar shadows must be confirmed by lateral X-rays. Common causes of hilar enlargements are; bronchogenic carcinoma, lymph node enlargement and dilatation of pulmonary arteries. Lymph node enlargement is typically lobulated and may extend up to the paratracheal glands. Bronchogenic carcinoma, tuberculosis, lymphoma and sarcoidosis may cause hilar lymphadenopathy. Whereas, sarcoidosis causes bilateral symmetrical lymph node enlargement, in lymphoma there will be bilateral and asymmetrical enlargement of the nodes. Tuberculosis and metastatic carcinoma will produce unilateral lymph node enlargement. Rarely, silicosis, glandular fever, fungal infections, generalized drug reactions and berylliosis can produce hilar lymph node enlargement. Enlarged pulmonary arteries are due to cor pulmonale secondary to chronic obstructive pulmonary disease, mitral valve disease, and left to right shunts, multiple pulmonary thromboembolism, aneurysms and

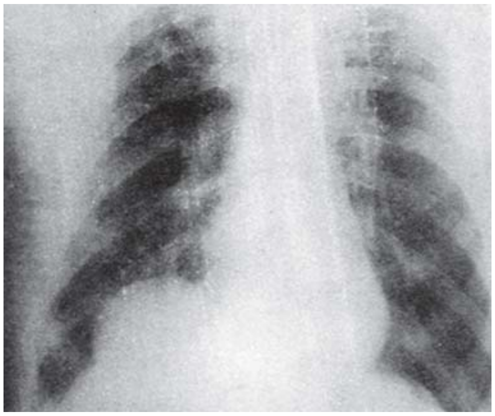

Fig. 24.100: Pericardial cyst right common site in the cardiophrenic angle

poststenotic dilatation in pulmonary stenosis. It may be idiopathic also. Some of the X-ray pictures of hilar enlargement are shown in Figures 24.95 to 24.99.

Mediastinal enlargement will be dealt with in more detail in the chapter on mediastinum. Briefly, the anterior mediastinal shadows are due to dermoid cyst, thymoma, intrathoracic goiter, hernia through the foramen of Morgagni, bronchogenic carcinoma and lymphoma; middle mediastinal lesions include hilar nodes, bronchogenic cyst, cystic hygroma, pericardial cyst (Fig. 24.100) and lipomas; and lesions in the posterior mediastinum are mostly neurogenic tumors. Other lesions in the posterior mediastinum are hiatus and Bochdalek's hernia, esophageal dilatation due to achalasia and aneurysm of the aorta.

Pleural lesions will be discussed in the chapter on pleural diseases.

Pulmonary Imaging: Systematic Approach to Interpretation of Computed Tomography of the Chest

Rubal Patel, Rakesh Shah, Sabiha Raoof, Suhail Raoof

INTRODUCTION

Computed Tomography (CT) was discovered independently by Sir Godfrey Hounsfield and Dr Alan Cormack in the 1970s and has undergone substantial advancement corresponding to the progression of modern computer technology. CT has become a fundamental part of clinical decision making. Technologic developments in CT have significantly influenced the diagnostic approach to many clinical diseases and expanded the indications for thoracic imaging. This chapter focuses on a comprehensive review of the diagnostic and interpretative findings seen on CT imaging. It is broken down into three general parts: (1) the technical aspects of CT imaging with a summary of the special features and clinical indications of each technique; (2) normal components of the pulmonary parenchyma, airways and pulmonary vasculature with a description of specific radiographic signs pertaining to each component; and (3) diseases involving the tracheobronchial tree, pulmonary parenchyma, mediastinum and a mention of a few miscellaneous conditions.

TECHNICAL ASPECTS

In general, CT provides comparatively more information than plain radiography. It provides good contrast between tissues allowing for detection of even subtle differences between tissues. Plain radiographs detect differences in the contrast of about 5%, whereas CT can detect differences of less than 0.5%. Images on CT are free of superimposition of structures, thereby eliminating the effects of overlapping anatomy. Images can be obtained rapidly with a wide field of view and an ability to provide cross-sectional images of the thorax. CT can localize diseases seen on conventional radiography, assist in the guidance of interventional procedures, can contribute new information or detect unsuspected abnormalities.

Disadvantages of CT include the exposure to more radiation than plain chest radiography; requirement of patient transport to the CT scanner, which may be difficult in critically ill patient; and the risk of intravenous contrast administration. The wide range of indications for CT and unlimited variation of pathologic presentations make it essential to alter each CT examination to the clinical diagnosis in question. There are several technical parameters, such as slice thickness, scan times, pitch, reconstruction intervals and window settings that can be selected. In general, three modes of CT imaging are currently in practice: Conventional CT, high-resolution CT and volumetric or spiral/helical CT.

Conventional CT

It provides multiple contiguous cross-sectional images (greater than 2 mm thick) through the thorax while the patient is stationary with table position incremented between acquisitions. Narrower collimation of 5 mm may be utilized when scanning through the hilar regions, and 1 to 2 mm to demonstrate small pulmonary nodules and for high resolution CT of the lung parenchyma. Conventional CT is broadly accepted and available for the work-up of many pulmonary conditions. Disadvantages of conventional CT include the motion artifact and loss of details from volume averaging.

Multislice CT

It has largely replaced single slice scanners and allows for extended anatomic coverage and shorter examination times.[1] Several hundred image slices are generated in less than a minute. Depending on the type of multislice CT scanner, images can be scanned up to 64 times faster than single slice CT scanners. Consequently, they can cover more patient length per unit time, a predetermined scanning volume, or the same volume in the same time with thinner slices. The entire chest can be scanned in less than 10 seconds. There is improved temporal and spatial resolution with thinner sections and greater contrast enhancement. Diagnosis of vascular abnormalities, such as subsegmental pulmonary emboli, characterization of small pulmonary nodules and the recognition of airway disease are significantly improved. The distribution and morphology of diffuse lung disease is better illustrated with 1 mm collimation and can be viewed in the coronal and sagital planes.

Reconstruction images are created by workstations that have a range of computer software programs and processing tools, which determine the quality or characteristics of the image. The reconstruction of CT data sets obtained on multislice scanners may result in several (1,000–5,000) images per examination. This makes it difficult to extract all the information present by using standard two-dimensional techniques. Therefore, post processing volume imaging and 3-D image display are crucial to volume visualization. Various software and workstation designs are available to improve volume visualization. Techniques, such as volume rendering and maximum intensity projection, which are computer-implemented algorithms, are used to transform serially acquired axial CT image data into 3-D images.

High-Resolution CT (HRCT)

It shows very thin (less than 2 mm) cross-sectional images at 10 or 20 mm intervals (noncontiguous) with high spatial resolution, allowing for detailed analysis of lung structure. This provides more detail than conventional CT scanning. The basic lung unit that is visible on HRCT is the secondary pulmonary lobule, around which many pathologic processes can also be visualized.[2] HRCT is particularly helpful in the detection of metastatic lesions, solitary pulmonary nodules, bronchiectasis and characterization of interstitial lung diseases, where detailed assessment is necessary.[3] It can provide an accurate assessment of the configuration, distribution, and even the degree of disease activity and potential reversibility of diffuse lung disease and has shown to have a correlation between radiographic and histopathologic appearances. The pattern of scanning may be specified to the suspected diagnosis. For instance, scanning should be performed at 1 cm intervals for diffuse lung disease, but should be limited to the involved area in focal lung processes and solitary pulmonary nodules.

Helical (Spiral or Volumetric) CT

Helical CT scanning is one major technical development in CT scanning. It provides multiplanar images of the entire chest during a single breath-hold (8 to 10 seconds), while the patient is moved continuously through the CT gantry with continuous rotation of the X-ray tube and detector assembly. The main advantages include speed, less radiation exposure, and an ability to retrospectively construct 3-dimensional images. Respiratory motion is eliminated and volumetric data can be manipulated to obtain overlapping axial sections without additional radiation to the patient.[4] However, the requirement for breath-holding may not be feasible for patients with symptomatic pulmonary disease. It is useful in the evaluation of mediastinal abnormalities.

CT Angiography

CT angiography is obtained during a 15 to 30 second helical scan. The influx time of the contrast medium and the degree of vascular and parenchymal enhancement are dependent upon the concentration of contrast material, the rate of injection, and the cardiac output. It is exceedingly effective in the diagnosis of pulmonary embolism. Several studies have confirmed comparable results of CT angiography to conventional pulmonary angiography.

The special features, advantages and disadvantages and clinical indications of these techniques are summarized in Table 25.1.

NORMAL COMPONENTS OF THE PULMONARY PARENCHYMA

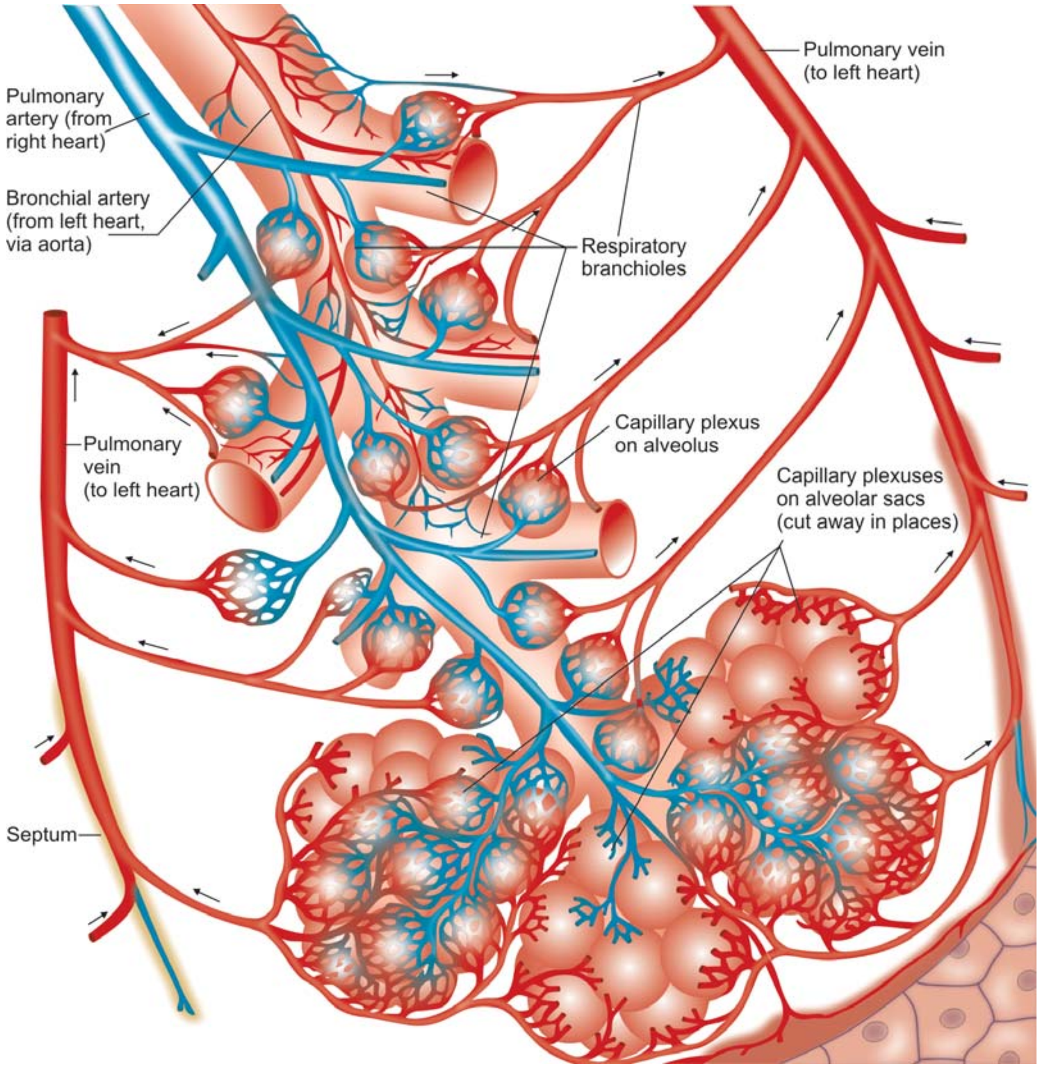
A strong knowledge of lung anatomy is necessary to understand the CT features of lung diseases. It allows for better understanding of the pattern of the disease, as well as its specific distribution in the lung. The lung is composed of anatomical elements of similar architecture at gradually smaller sizes. These include lungs, lobes, segments, subsegments, secondary lobules and acini. Each division is organized around central supporting structures, such as airways and arteries and peripheral

TABLE 25.1: Clinical indications, special features, advantages and disadvantages of various techniques of CT chest imaging

CT Technique	*Indications*	*Special Features*	*Advantages/Disadvantages*
Conventional	Work-up of many pulmonary conditions: • Localization and characterization of mediastinal mass • Staging of Lung Cancer • Detection of pulmonary metastases approach for biopsy	• Provides multiple contiguous cross-sectional images • Allows for scanning throughout the thorax	• Susceptible to motion artifact • Loss of detail from volume averaging
Multislice	Diagnosis of vascular abnormalities: • Subsegmental pulmonary emboli • Characterization of small pulmonary nodules • Evaluation of airway disease	• Improved resolution • Improved contrast enhancement • Ability to create retrospective reconstructions • Thinner sections	• Faster imaging • Less motion artifacts • Greater anatomic coverage
HRCT	Evaluation and detailed characterization of: • Solitary pulmonary nodule • Interstitial lung disease • Bronchiectasis • Metastatic lesions	• Thinner cross-sectional images • Provides more detail than conventional CT scanning	• Accurately assessment of the pattern and distribution of diffuse lung disease • Characterization of disease activity • Guidance for lung biopsy • Does not provide contiguous images – skips areas between the thin sections
Helical	Evaluation of various thoracic injuries: • Aortic dissection • Pneumothorax • Pulmonary contusions and lacerations • Tracheobronchial injury • Skeletal injuries such as rib, sternal, vertebral fractures • Diaphragmatic injuries	• Increased scanning speed • Improved vascular enhancement • Thinner collimation • Acquires volumetric data of the thorax, allowing for manipulation of image data • Able to generate high quality multiplanar 2-D and 3-D reconstructions	• Capable of scanning large volumes of tissue during a single breath hold • Minimizes motion artifact • Generates high quality images with the ability to show branching or oblique airway or vascular anatomy • Assists in surgical planning
CT Angiogram	Detection and evaluation of vascular abnormalities: • Aortic disease • Pulmonary embolism	• Requires rapid intravenous injection of contrast material • Ability to use volume rendering to improve diagnostic accuracy • Technical details may be manipulated to obtain optimal vascular studies	• Proper injection timing is essential to ensure imaging at the time of peak intravascular enhancement • The volume of contrast used should be adequate to maintain maximal vascular opacification throughout the spiral acquisition • With optimal technique, CT angiography can provide accurate images, eliminating the need for conventional angiography

supporting structures, such as pleura and connective tissue septa[5] (Fig. 25.1).

The support system of the lung consists of a network of connective tissues, which forms the interstitium. It maintains a strong structural support for the airways, blood vessels and alveoli, but is also thin enough to allow for gas exchange. The interstitium can be divided into three components that communicate freely: The peripheral, axial and parenchymal connective tissue[6] (Fig. 25.2). The peripheral connective tissue extends from the lung pleura to the lung septa. The septa are incomplete partitions within the lung that divide the lung segments, subsegments and secondary pulmonary lobules and acini. The axial connective tissue stems from



Pulmonary artery (from right heart)
Bronchial artery (from left heart, via aorta)
Pulmonary vein (to left heart)
Respiratory branchioles
Pulmonary vein (to left heart)
Capillary plexus on alveolus
Capillary plexuses on alveolar sacs (cut away in places)
Septum

Fig. 25.1: Anatomic components of the lung. The centrilobular structures consist of the terminal bronchiole and pulmonary artery. The peripheral structures are composed of the pulmonary veins and the lymphatic system. This structural organization is present from the largest to the smallest lung unit (Netter illustration from www.netterimages.com. © Elsevier Inc. All rights reserved)

the hilum and surrounds the bronchovascular structures, extending peripherally. The parenchymal connective tissue is located in between the alveoli and capillaries, where gas exchange takes place. It extends to the axial and peripheral connective tissues.[6]

The normal segmentation of pulmonary lobes includes three (upper, middle and lower) in the right lung and two (upper and lower) in the left lung. They are separated by interlobar fissures. Lobes are identified on CT by the visualization of interlobar fissures or an avasular plane on which they lie, or by identifying bronchial branches that lead to the corresponding lobes.[7] Pulmonary segments and subsegments are not as easily discerned as lobes. At the subsegmental level, of the three units of lung structure present, i.e. the primary pulmonary lobule, acinus and secondary pulmonary lobule, the secondary lobule is the smallest unit of lung structure that is seen on HRCT bordered by interlobular septa[8] (Figs 25.3 and 25.4).

The secondary lobules are the building blocks around which CT patterns are constructed. These structures are extremely important in the interpretation of lung changes seen on CT. The interpretation of HRCT is exceptionally useful for the diagnosis of various diffuse and focal lung diseases, which are centered around the secondary pulmonary lobule. Therefore, a good knowledge of the anatomy of the secondary lobule is essential to determine

Pulmonary arteries (1 mm)
Visceral pleura (0.1 mm)
Interlobular septa (0.1 mm)
1 cm

Fig. 25.5: The secondary pulmonary lobule. Each secondary lobule is made up of a small bronchiole and pulmonary artery and bordered by interlobular septa, where a pulmonary vein and lymphatic branches reside[10] (Raoof S, Amchentsev A, Vlahos I, et al. Pictorial essay: mulitinodular disease: a high-resolution CT scan diagnostic algorithm. Chest. 2006; 129(3):805-15)

the distribution pattern of the disease. Differential diagnosis of lung disease can be limited by the evaluation of whether the disease is located in or around the airways, the blood vessels, the lymphatics or the lung interstitium.[9]

The Secondary Pulmonary Lobule

The secondary pulmonary lobules are polyhedral in shape and differ in size from 1.0 to 2.5 cm and are formed by a collection of acini.[2,6,9] The reported number of acini that form a secondary pulmonary lobule vary considerably, a range of 3–12 have been described. An acinus is the largest lung unit where all airways participate in gas exchange. Each secondary lobule is made up of a small bronchiole and pulmonary artery, and bordered by interlobular septa, where a pulmonary vein and lymphatic branches reside[9,10] (Fig. 25.5).

Interlobular Septa

The secondary lobules are surrounded by interlobular septa made by connective tissue. The lymphatic system draining the visceral pleura, courses within the interlobular septa along with the septal veins leading to the lymphatics and nodes within the hila. The interlobular septa measure 0.1 mm in the subpleural location, are much thinner and less defined in the center.[2] The thickness of the peripheral interlobular septa are at the lower limit of HRCT resolution, may or may not always be seen, especially in CT scans of normal patients.

Centrilobular Region

The central part of the secondary lobule contains the peribronchovascular interstitium that surrounds the terminal pulmonary artery and the terminal bronchial branches.[9] It is difficult to discern the bronchial or arterial structures and the HRCT appearance of these structures is dependent on their size. A linear, branching or dot-like opacity usually seen within the center of the lobule represents the intralobular artery branch and its distributions.[2] The centrilobular arteries are not seen to extend to the pleural surface. The airway wall thickness determines the visibility on HRCT. The wall thickness of a normal terminal bronchiole measures 0.1 mm, which is below the resolution of HRCT.[11] Therefore on HRCT imaging, intralobular bronchioles are not usually identified and are not normally seen within 1 cm of the pleural surface.

Specific Signs

The diagnostic approach for HRCT relies upon a good understanding of lung anatomy in general, particularly the secondary pulmonary lobule; the pattern and the distribution of disease; and on associated findings, such as pleural plaques, calcifications, thickening, effusions, lymph node enlargement and the clinical history.

The principal parenchymal patterns seen on HRCT include reticular and nodular structures, increased opacity (ground-glass and air space filling or consolidation), and decreased opacity, including cystic lesions, mosaic attenuation and air trapping.[5] Accompanying findings include linear opacities, parenchymal bands and architectural distortion (Fig. 25.6)

Reticular Patterns

Reticular opacities occur with thickening of the pulmonary interstitium by fluid, fibrosis, or other infiltrative processes (Fig. 25.7). The reticular pattern can be coarse, intermediate or fine. The coarse reticular pattern (1 cm) is due to the thickening of interlobular septa, intermediate reticular changes are seen with honeycombing, and fine reticular changes are seen with intralobular septal thickening. The reticular pattern may be smooth, nodular or irregular.

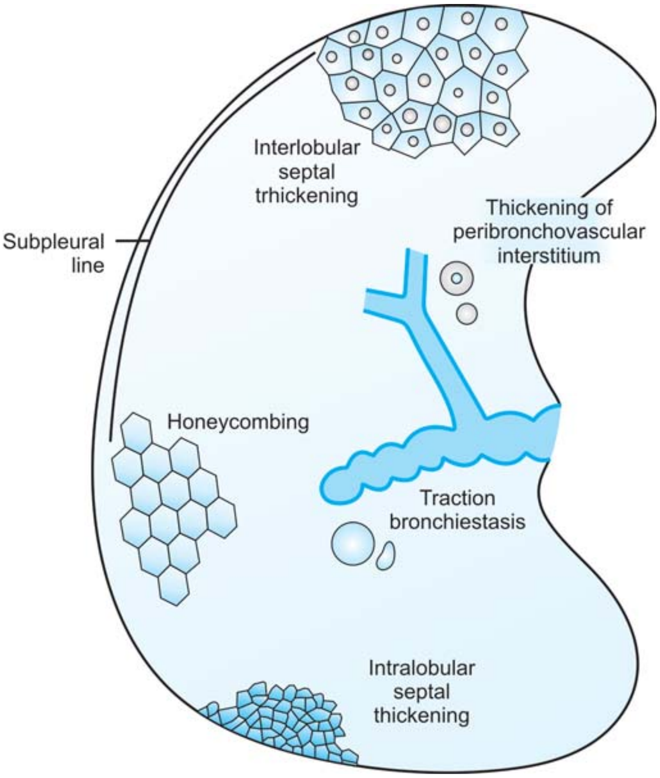

Fig. 25.6: Pictorial representation of reticular opacities: Thickening of the peribronchovascular interstitium, interlobular septal thickening, honeycombing and traction bronchiectasis

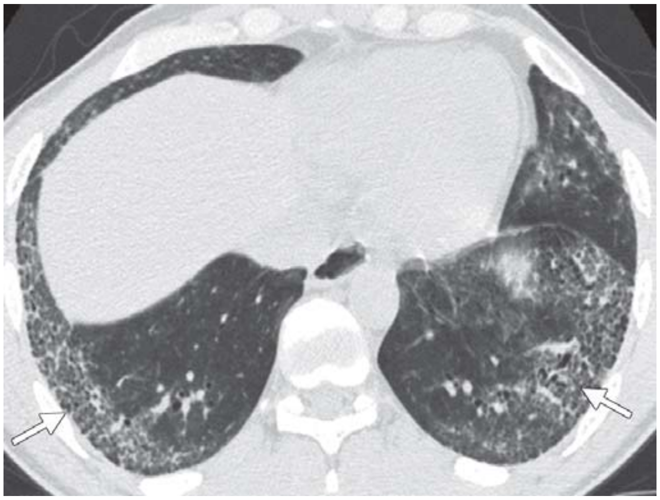

Fig. 25.7: HRCT through the lung bases showing subpleural reticulation in a patient with idiopathic pulmonary fibrosis. Also visible are small cysts (arrows) from honeycombing

The interface sign: It is the most common and earliest HRCT abnormality found in interstitial disease with an irregular and thickened appearance of the normally smooth septa bordering the parenchyma with vessels, bronchi and visceral pleura.[5] It is however a nonspecific sign of interstitial diseases. Other findings include interlobular septal thickening, peribronchial thickening, intralobular linear opacities and cysts.

Interlobular septal thickening: It is a characteristic finding of interstitial lung disease. They appear as 1–2 cm lines that are perpendicular to the pleura and extend out to the pleural space. Centrally they form polygonal structures outlining the secondary lobules (Figs 25.4 and 25.6).

Peribronchial or perivascular interstitial thickening: It results from thickening of the connective tissue surrounding the bronchi or pulmonary vessels. The thickening may be smooth or irregular. Dilatation of the bronchi may result in cases where surrounding fibrosis results in traction, known as traction bronchiectasis (Figs 25.6 and 25.8).

Intralobular linear opacities: It occurs with the thickening of the interstium within the secondary pulmonary lobule. This forms a fine reticular pattern with small irregular lines separated by only a few millimeters. This pattern is most commonly caused by fibrosis, the distribution (upper vs lower lobes) and associated findings vary with different diseases.

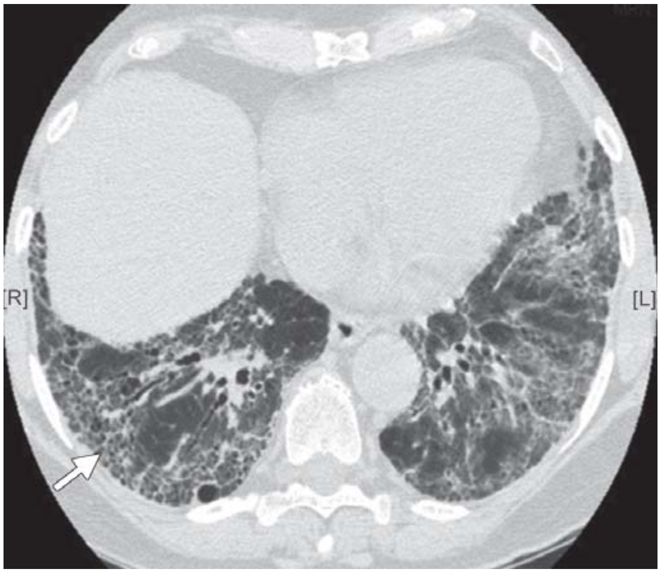

Fig. 25.8: HRCT through the lower lung zones showing honeycombing (arrow) with dilated non-tapering bronchi especially on the right side (traction bronchiectasis) and architectural distortion

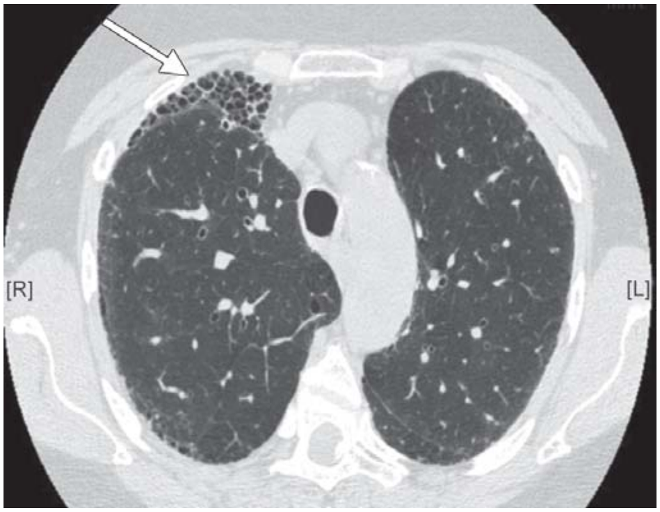

Fig. 25.9: HRCT through the upper lung zones demonstrating numerous cysts (arrow) involving the subpleural regions resulting in honeycombing. Note dilated bronchi adjacent to branches of the pulmonary artery

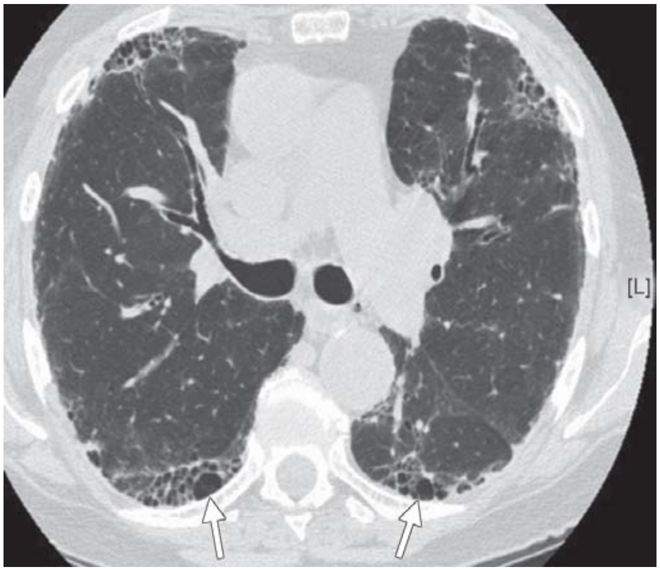

Fig. 25.10: HRCT demonstrating cystic changes in the subpleural regions (arrows) resulting in a honeycombing pattern in a patient with idiopathic pulmonary fibrosis. Note dilated bronchi (right upper lobe dilated bronchi) and paucity of ground glass opacity

Cysts: These are rounded air-containing spaces surrounded by well-defined walls. When they are 4–5 mm in size and present in the subpleural region, they represent honeycombing in end-stage fibrosis and are associated with traction bronchiectasis and architectural distortion (Figs 25.9 and 25.10).

Nodules

Nodules of less than 1 cm may be seen in several acute and chronic infiltrative lung diseases. Nodular patterns include airspace lesions with ill-defined or ground-glass borders, and interstitial nodules with sharp, hazy or stellate margination.[7] The distribution of nodules is useful in narrowing the differential diagnosis.[10] Nodules may predominantly follow a perilymphatic, centrilobular or random distribution. The perilymphatic nodules are found along the bronchovascular interstitium, interlobular septa and subpleural areas. Centrilobular nodules are usually poorly defined and are seen in the center of each secondary lobule. Random nodules are due to hematogenous spread, usually well-defined and randomly situated in the lung.

Increased Opacities

Ground glass opacification: A ground glass opacity refers to the presence of either a *focal or diffuse hazy* increased attenuation of the lung, which does not obscure the vascular or bronchial structures and is not associated with air bronchograms[12] (Figs 25.11 and 25.12). It is caused by partial filling of the airspace. Although ground glass attenuation is a nonspecific sign, it represents an active process, which may potentially be treated or reversed.[13]

Consolidations or airspace filling defects: Parenchymal consolidation or airspace filling causes opacification with the obscuration of vascular structures accompanied by air bronchograms. These two features differentiate it from ground-glass changes (Figs 25.13 and 25.14). These changes result from replacement of alveolar gas by pus, edema, blood or cells.[13]

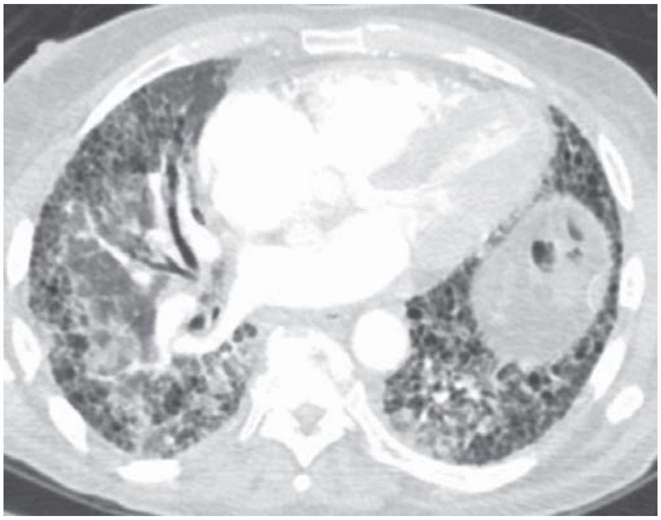

Fig. 25.11: HRCT through the basilar lung showing areas of extensive ground glass attenuation, honeycombing and peribronchial thickening

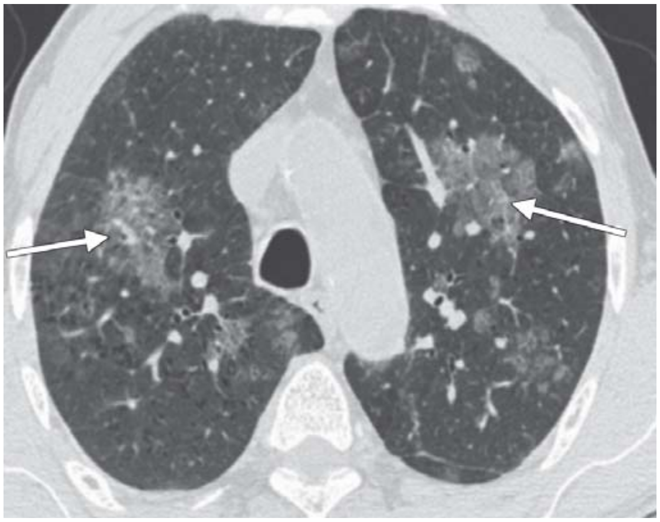

Fig. 25.12: High resolution CT scan of the upper lung zone demonstrating patchy ground glass attenuation (arrows) in a patient with desquamative interstitial pneumonia

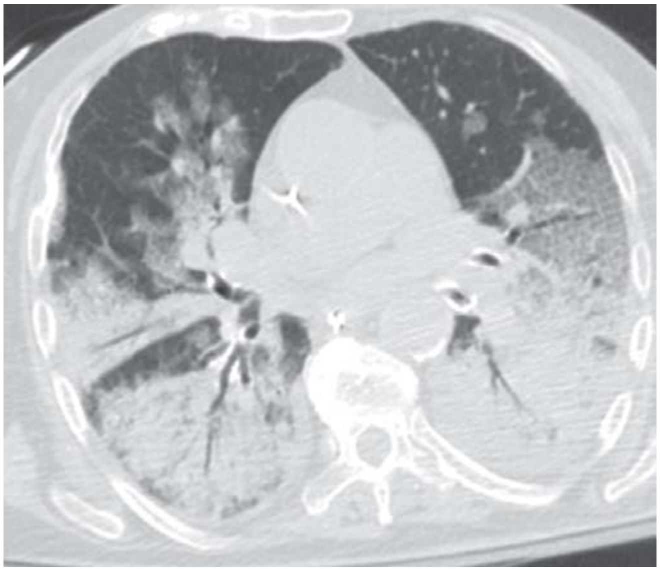

Fig. 25.13: CT chest through mid-lung showing bilateral dense opacity with air bronchograms. This is typical of air space disease

Decreased attenuation: Decreased lung attenuation can occur from lung damage, e.g. emphysema or diminished blood flow, e.g. pulmonary vascular or airway abnormalities.

In emphysema, areas of abnormally low attenuation develop that may have no identifiable walls[14] (Figs 25.15

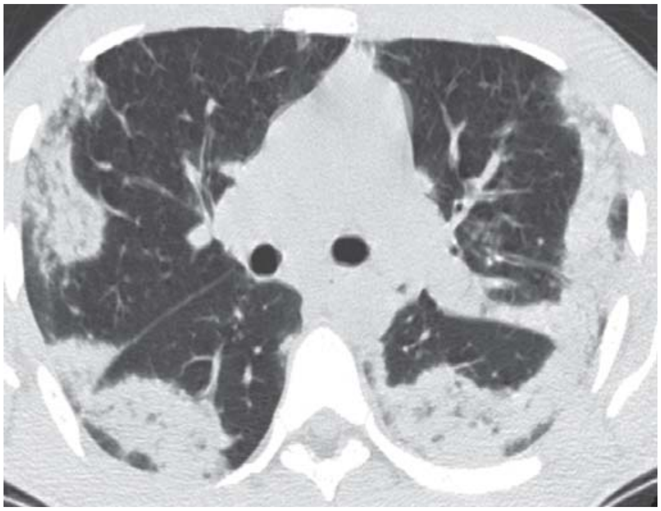

Fig. 25.14: HRCT chest at the level of the main stem bronchi illustrating dense bilateral opacities in a peripheral distribution. The patient had chronic eosinophilic pneumonia

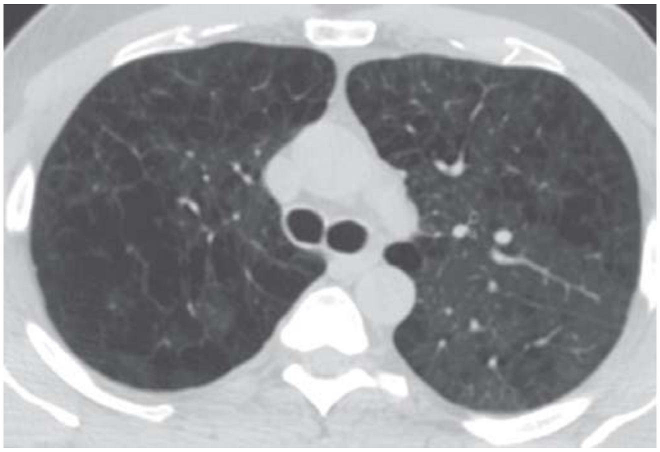

Fig. 25.15: CT chest through the upper lobes showing focal areas of decreased attenuation. No definable walls are visible in these focal areas of hyperlucency. This patient was a smoker with centrilobular emphysema

and 25.16). There are three main forms of emphysema: centrilobular, panlobular and distal acinar emphysema.

Low attenuated areas may also result from decreased perfusion arising from blood flow redistribution in vascular obstruction or airway abnormalities. Redistribution of blood flow away from the areas of vascular obstruction or airway obstruction leads to increased attenuation in the areas of normal lung parenchyma. This pattern of variable regional areas of decreased and increased attenuation due to regional differences in perfusion is termed mosaic attenuation[12] (Fig. 25.17). The two processes, i.e. vasculature versus airway abnormalities may be differentiated by performing expiratory CT.[15] Airway disease will show no change in the lucent areas where there is air trapping, whereas in primary vascular disease, the attenuation in both the hyperlucent and hypolucent areas will increase equally on end expiration. The differentiation of mosaic attenuation (due to blood flow redistribution) from true ground-glass attenuation can be accomplished by evaluating the vessel size in the

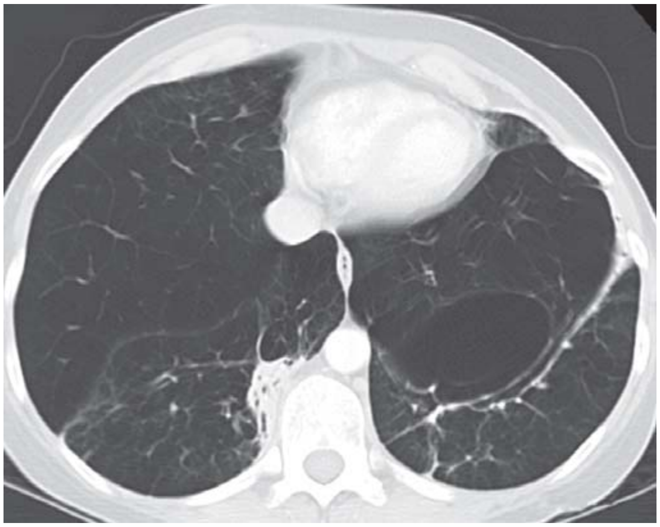

Fig. 25.16: CT chest through the lower lobes showing extensive panlobular emphysema in a patient with alpha 1 antitrypsin deficiency

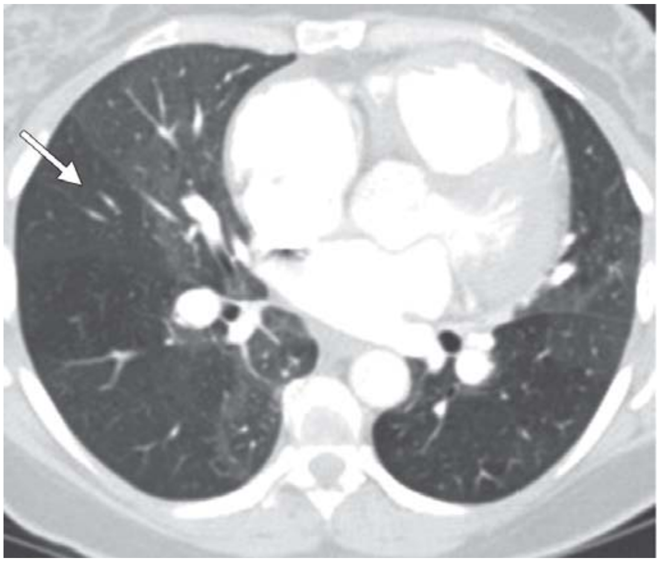

Fig. 25.17: CT chest through the lower lobes demonstrating a pattern of variable regional areas of decreased and increased attenuation, also known as mosaic attenuation. This patient had chronic thromboembolism. Note the decreased vascularity in the hypolucent areas of the lung (arrow)

TABLE 25.2: Differential diagnosis of mosaic attenuation

Abnormality	*Causes*	*Caliber of Vessels*	*Effect of Exhalation*
Small airways disease	• Asthma • Bronchiolitis obliterans • Cystic fibrosis	Decreased size and number of vessels in hypo-attenuated areas due to regional air trapping and hypoxic vasoconstriction	Unequal attenuation in the hyperlucent and hypolucent areas No change in hypolucent areas (air-trapping)
Small vessel disease	• Chronic pulmonary embolism	Decreased size and number of vessels in hypo-attenuated areas due to obliteration of small vessels	Attenuation in both the hyperlucent and hypolucent areas will increase equally (no air-trapping)
Infiltrative disease	• Pneumocystis jiroveci pneumonia • Eosinophillic pneumonia • Hypersensitivity pneumonia	Equal size and number of vessels in areas of increased and decreased attenuation	Attenuation in both the hyperlucent and hypolucent areas will increase equally (no air-trapping)

increased and decreased areas. In infiltrative lung disease, the vessel size and number will be equal in the areas of increased and decreased attenuation. In airways or vascular disease, vessel size and number will be decreased in the regions of hypo attenuation.[15] These findings are summarized in Table 25.2.

NORMAL LUNG COMPONENTS OF THE AIRWAYS

The airways divide by asymmetric dichotomous branching with approximately 23 generations of branches from the trachea to the alveoli that become thin walled as they branch. The accuracy of CT to evaluate the central airways is well established.[16]

Trachea

The trachea is a cartilaginous structure extending from the inferior border of the cricoid to the carina. It may be divided into extrathoracic and intrathoracic segments along the manubrium and is approximately 10–12 cm in length.[17] There are 16 to 22 cartilaginous horseshoe-shaped rings that form the trachea anteriorly. The posterior portion of the trachea consists of a thin fibromuscular membrane, without cartilage. The blood supply to the trachea comes superiorly from the branches of the inferior thyroid artery and right intercostal artery and inferiorly from the bronchial arteries and third intercostal artery (Fig. 25.18). The cross-sectional appearance of the trachea may be oval, rounded or horseshoe shaped (Fig. 25.19). The average tracheal diameter in men is 19.5 mm and in women 17.5 mm.[18] The shape of the trachea may vary with expiration, resulting in a cresenteric shape during forceful expiration, due to posterior tracheal bowing.[19]

Fig. 25.18: Arterial blood supply to the larynx and upper trachea. (F. Charles Brunicardi MD, FACS, ed. 2010. Schwartz's Principles of Surgery. New York. McGraw-Hill Health Professions Division)

The trachea splits into main bronchi, which divide into lobar bronchi. The lobar bronchi divide into segmental bronchi, which ultimately branch into subsegmental bronchi. After several more divisions at this level, the terminal bronchi emerge to give rise to the bronchioles.

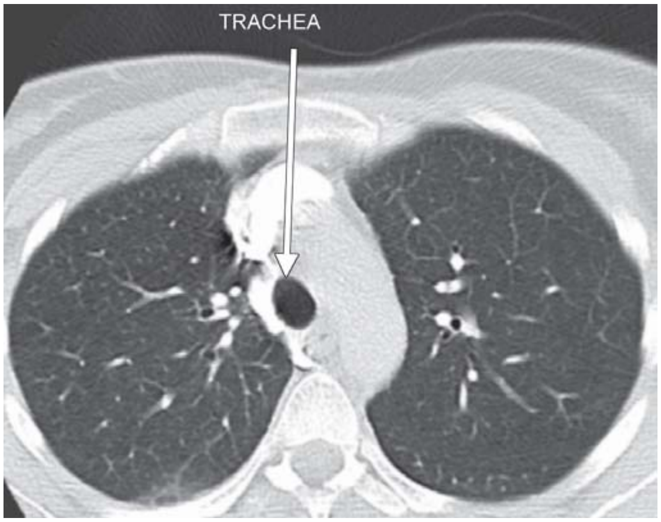

Fig. 25.19: CT chest through the upper lobes demonstrating normal oval tracheal lumen during inspiration

Bronchi

The bronchi are also composed of cartilaginous and fibromuscular structures, but the distribution is less regular than the trachea. They become more difficult to see in the periphery of the lung. Bronchi contain cartilage and glands within their walls, unlike bronchioles. Bronchioles can be divided into membranous bronchioles, which solely conduct air, and respiratory bronchioles, which have alveoli in their wall and are involved in gas exchange. Bronchioles along with corresponding pulmonary artery branches lie within the center of the secondary pulmonary lobule.

Evaluation of the airways should be done using spiral CT technique with thin collimation. The ability of CT to image a particular bronchus depends on its size and orientation relative to the scan plane. The main bronchi and bronchus intermedius are easily detected due to their large size. The origin of the proximal lobar and segmental bronchi can also be identified in most cases. Figure 25.8 illustrates the nomenclature of the bronchial tree (Table 25.3). Figures 25.20 to 25.26 illustrate the division of the bronchial anatomy as seen on spiral CT. The bronchi and large arteries usually run together, with their diameters being of approximate equal size. In general, airways of less than 2 mm in diameter or close to 1–2 mm to the pleural surface are below the resolution of HRCT images.[2] The presence of visible bronchial structures in the lung periphery signifies pathologic thickening or ectasia.

Specific Signs

Saber-Sheath Trachea

A "saber-sheath trachea" is a condition with marked reduction in the transverse diameter of the intrathoracic trachea greater than the half of the sagittal diameter (Fig. 25.27). It results from conditions such as chronic obstructive pulmonary disease.[20]

Tracheobronchomegaly

Tracheobronchomegaly results when the tracheal diameter increases and can be due to congenital or acquired disease[21] (Fig. 25.28). It is also known as Mounier-Kuhn syndrome and is commonly associated with tracheal diverticulosis, bronchiectasis and recurrent infections.

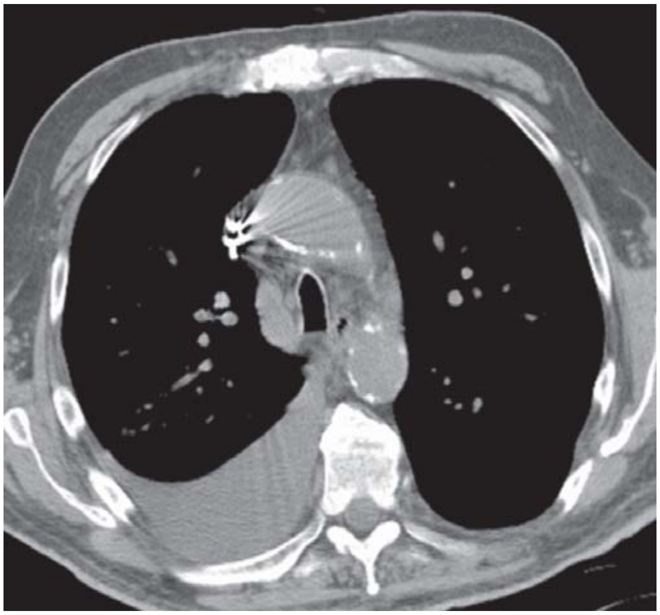

Fig. 25.27: CT chest showing marked reduction in the coronal diameter of the trachea as compared to the sagittal diameter indicating the characteristics appearance of a saber sheath trachea. Of note, there is a moderate sized pleural effusion on the right

Tracheal Diverticulosis

Tracheal diverticulosis results from the outpouching of the posterolateral tracheal wall secondary to weakness in the trachealis muscle. It may be congenital or acquired, and associated with recurrent infections and hemoptysis.[22]

Tracheobronchopathia Osteochondroplastica (TBO)

TBO is a rare benign condition of unknown etiology characterized by multiple submucosal osteocartilagous nodules involving the trachea and bronchi (Fig. 25.29). There is tracheal scalloping and nodularity with the irregular narrowing of the trachea. It spares the posterior tracheal membrane.[23]

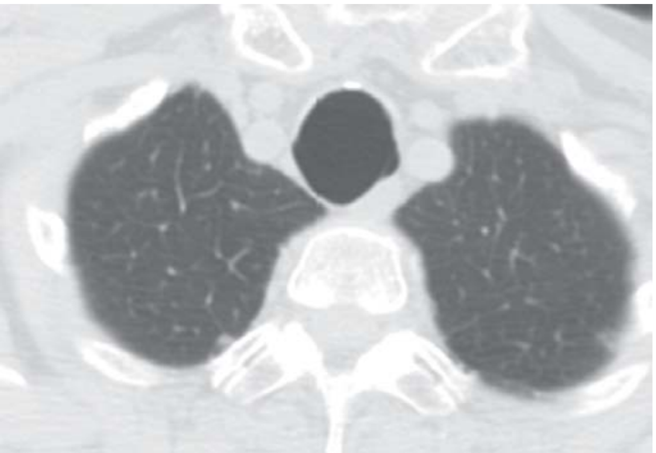

Fig. 25.28: CT chest showing an increased trachea diameter, resulting in tracheomegaly or Mounier-Kuhn syndrome. The normal tracheal diameter is 19.5 mm in a male and 17.5 mm in a female

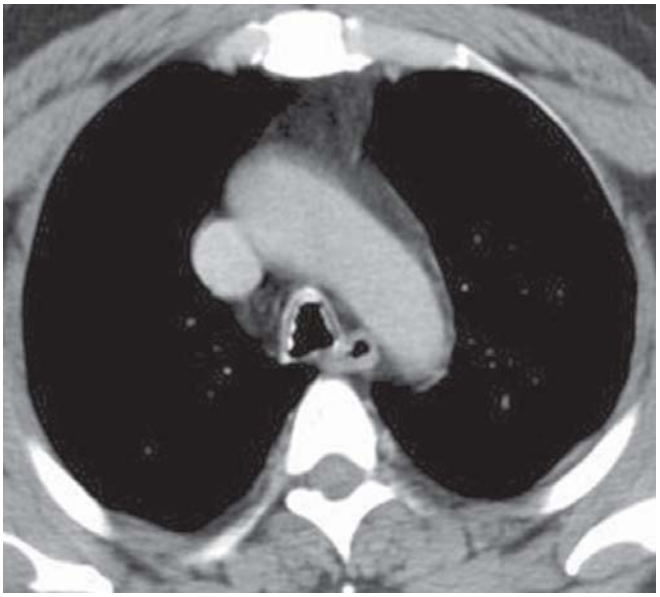

Fig. 25.29: CT chest section through the mid-trachea showing nodularity of the trachea with calcifications and sparing of the posterior tracheal wall, a characteristic finding in tracheobronchopathia osteochondroplastica

Tracheobronchomalacia (TBM)

TBM is a common and underrecognized cause of dyspnea and cough. It is a condition that results in excessive airway collapse of the tracheal and bronchial. By definition, in

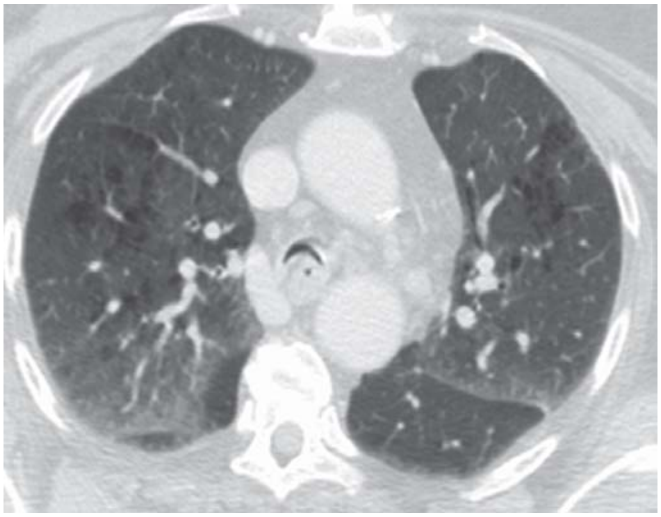

Fig. 25.30: CT chest in exhalation, showing excessive airway collapse with posterior bowing resulting in tracheomalacia

patients with TBM, the cross-sectional area of the trachea shows a reduction of at least 50% during quiet breathing, forming a crescent shaped airway (Fig. 25.30). It can result from several etiologies, including but not limited to external trauma, postintubation, chronic obstructive pulmonary diseases and chronic inflammatory diseases such as relapsing polychondritis. It is best diagnosed by paired inspiratory and expiratory dynamic CT imaging.[24]

NORMAL LUNG COMPONENT OF THE PULMONARY VASCULATURE

A comprehensive knowledge of the cross-sectional anatomy of the pulmonary arteries and veins is imperative in the diagnosis of vascular abnormalities and precise interpretation of CT images. The arteries accompany the airways and their pattern of division is similar to the branching of airways.

Pulmonary Arterial Anatomy

The main pulmonary artery begins from the base of the right ventricle, extends superiorly dividing into the right and left pulmonary arteries. These central pulmonary arteries are intrapericardial. Pulmonary arteries are elastic and thin-walled vessels. The main pulmonary artery on CT is the most anterior vascular structure arising from the heart. It is slightly smaller than the ascending aorta in normal subjects, measuring on average 28 mm in diameter.[25] This measurement is best taken at its bifurcation, lateral to the aorta in the short axis of the pulmonary artery. CT measurements of the pulmonary artery have been shown to correlate with pulmonary artery pressure.[25]

The main pulmonary artery divides lateral to the ascending aorta into the right and left pulmonary arteries. The right pulmonary artery arises nearly at a right angle and passes posteriorly to the ascending aorta and anteriorly to the right main bronchus as it crosses the mediastinum. It is seen along its length on CT since it lies in the scan plane. The left pulmonary artery appears as a direct communication of the main pulmonary artery. It passes slightly to the left of its origin and arches over the left main bronchus as it enters the hilum. The right and left pulmonary arteries are usually of equal size.

Similar to bronchial division, the pulmonary arteries divide by dichotomous branching. There are approximately 17 divisions from the bifurcation of the main pulmonary artery to arteries of a diameter of 10–15 mm.[26]

The right main pulmonary artery usually divides into an ascending trunk; trunchus anterior, primarily supplying the right upper lobe; and a descending trunk and interlobar branch, supplying mainly the right middle and lower lobes. The left pulmonary artery usually continues as the descending or interlobar left pulmonary artery, giving rise to segmental branches of the left upper and lower lobes (Fig. 25.31). The branching of the lobar, segmental and subsegmental pulmonary artery branches show considerable variation and are sometimes identified

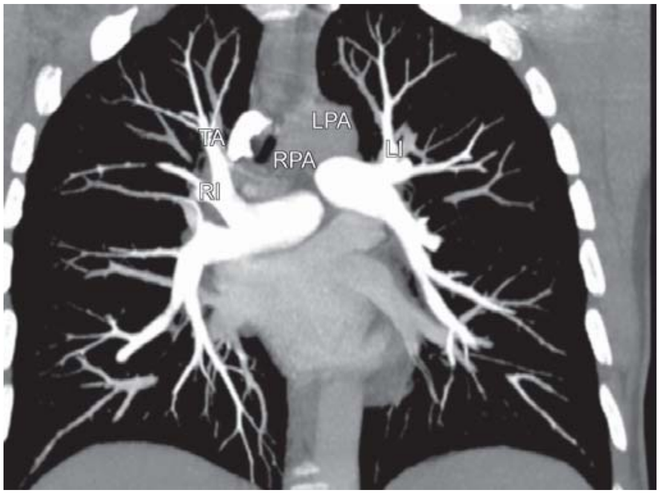

Fig. 25.31: Coronal image of CT chest showing normal hilar pulmonary artery branching. The right main pulmonary artery (RPA) divides into an ascending trunk, trunchus anterior (TA), primarily supplying the right upper lobe, and a descending trunk, interlobar branch (RI), supplying mainly the right middle and lower lobes. The left pulmonary artery (LPA) continues as the descending or interlobar left pulmonary artery (LI), giving rise to segmental branches of the left upper and lower lobes

by associated bronchi. Occlusion of segmental pulmonary arteries can easily be identified on CT, whereas subsegmental pulmonary arteries occlusion may not always be visualized.

Pulmonary Veins

The pulmonary veins arise from alveolar capillaries, where pulmonary venules form. Pulmonary veins run through the interlobular septa and then through the more central connective tissue sheaths to the left atrium.[27] The branching patterns of veins are more variable, but generally two superior and two inferior pulmonary veins are found on each side.

Bronchial Arteries

The bronchial arteries belong to a different arterial system that originates from the systemic circulation. They accompany the bronchi to the level of the terminal bronchi, where they ramify into pulmonary plexus and are drained by the pulmonary venous system.

Abnormalities

Pulmonary Artery Agenesis

Congenital abnormalities resulting in embryonic disappearance of the proximal segments of the right and the left sixth arch may result in the agenesis of either the right or left pulmonary artery respectively. It may occur as a separate condition or along with cardiac abnormalities. Features seen on CT include a small hemithorax, ipsilateral displacement of the mediastinum and absence of the analogous pulmonary artery.[28]

Anomalous Pulmonary Artery

An anomalous retrotracheal left pulmonary artery is seen on CT to arise from the right pulmonary artery, looping behind the trachea and right main stem bronchus before reaching the left hilum. This can result in symptomatic compression of the right main stem.[29]

Anomalous Pulmonary Vein

Anomalous pulmonary vein abnormalities results in the drainage of blood completely or partial into the right atrium.[30] The scimitar syndrome there is aberrant drainage of the right pulmonary artery into the inferior vena cava.

Pulmonary Embolism

Knowledge of the hilar vascular anatomy is crucial for the precise recognition of an acute pulmonary embolism. The identification of the pulmonary arteries is done using the bronchial anatomy as reference since the arteries tend to lie adjacent to the airways. The most consistent CT finding of a pulmonary embolism is an intraluminal filling defect (Fig. 25.32). Depending on the plane of the CT and orientation of the artery, these defects may appear as spherical, eccentric or serpiginous filling defects.[31] In large arteries they may also appear as free-floating masses. An acute pulmonary embolus forms an acute angle with the contrast-filled lumen. In chronic pulmonary embolism, the thrombi are smooth or irregular eccentric mural defects, representing organization of the thrombus.[32]

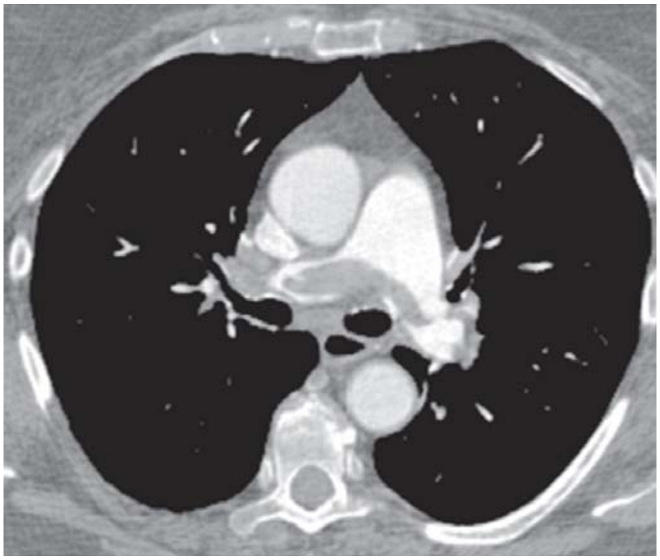

Fig. 25.32: CT angiogram showing a large filling defect at the division of the right and left main pulmonary arteries. This is also known as a saddle embolism. Note the acute angle formed by the embolus and the contrast filled lumen

Pulmonary Artery Aneurysm

Pulmonary artery aneurysms have been associated with a spectrum of conditions such as infections, congenital heart conditions, atrial and ventricular septal defects and vasculitis.[33] The primary cause of pulmonary artery aneurysm is cystic medial necrosis. A false aneurysm may also develop as a result of a pulmonary artery catheter. CT findings are often nonspecific and erroneously identified as masses, nodules or adenopathy.

Pulmonary Varix

Pulmonary varices may be easily identified on CT as an enlarged mass with aneurysmal dilatation of the pulmonary vein[34] (Fig. 25.33).

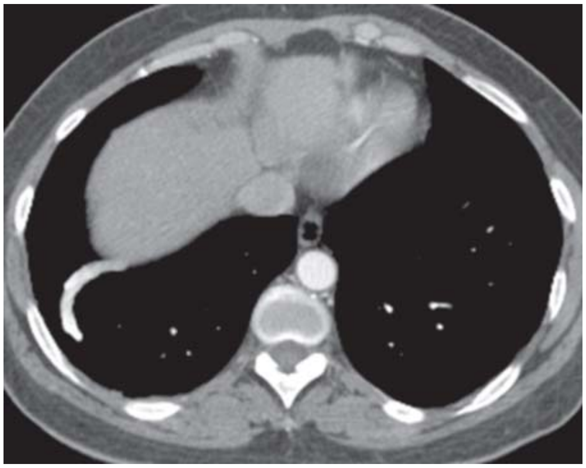

Fig. 25.33: CT chest with contrast showing a dilatation of the pulmonary vein from a pulmonary varix

TRACHEOBRONCHIAL DISEASES

Bronchiectasis

The definition of bronchiectasis is localized, irreversible dilatation of the bronchial tree.[12] Several conditions have been associated with bronchiectasis (Table 25.4). It commonly arises from acute, chronic or recurrent infections. Symptoms usually develop with severe disease and include a history of recurrent pulmonary infections, persistent productive cough or hemoptysis. The radiographic manifestations of bronchiectasis have been well studied. They include the loss of the clarity of vascular markings in specific lung segments, bronchial wall thickening; and in advanced bronchiectasis, distinct cystic masses, frequently demonstrating air-fluid levels.[35,36]

Bronchiectasis is classically described as *cylindrical, varicose, or cystic* based on appearance. Various other terms have also been used (Fig. 25.34). "Tram-tracks" are dilated airways coursing the scan plane. "Signet rings" describe cross-sectional dilated airways with adjacent pulmonary blood artery branches. "Beading airways" are saccular airways seen along their length. There are direct and indirect methods of diagnosing bronchiectasis on CT. Direct methods include bronchial dilatation, lack of normal bronchial tapering, and presence of airways in the periphery of the lungs. Indirect signs consist of bronchial wall thickening and irregularity and the presence of mucoid impaction within the airways.[36]

TABLE 25.4: Conditions associated with bronchiectasis

Disorders	*Description*
Focal distribution	
Bronchial obstruction	Foreign body Tumor Broncholithiasis Compression by peribronchial lymph nodes
Previous pneumonia

Bronchiolar Diseases

The introduction of HRCT on assessing small airway disease has significantly impacted the diagnosis and classification of bronchiolar disease.[37] Normal intralobular structures are beyond the resolution of CT, however direct and indirect signs of bronchiolar disease may be apparent (Flow chart 25.1). Direct signs include bronchiolar secretions, distinguished as branching Y-shaped linear densities; peribronchiolar inflammation, characterized by poorly defined centrilobular nodules; or bronchiolar wall thickening represented by focal small centrilobular lucencies. Indirect signs manifest as either the areas of mosaic attenuation on inspiration or as the areas of decreased attenuation on expiration.[38] Bronchiolar disease may be categorized on CT into four groups based on other associated signs.

Tree-in-Bud and Bronchiolar Disease

The characteristic finding in this category of bronchiolar disease is the finding of dilated, mucus-filled bronchioles, which result in a pattern of centrilobular nodular, as well as branching or Y-shaped densities, which imitate the appearance of a tree in bud.[39] This pattern is typically seen in the infectious bronchiolitis of several etiologies such as bacterial, viral and fungal causes. Common infections resulting in the tree-in-bud representation include mycobacterium tuberculosis infections, atypical mycobacterial infections, bacterial infections related to immunosupressive conditions such as HIV and cystic fibrosis.[38] It was initially described in patients with panbronchiolitis,[40] common in Asia. These patients have clinical symptoms of productive cough and dyspnea, with an obstructive impairment on pulmonary physiologic testing and characteristic ill-defined nodules and tree-in bud appearance on CT. Other proximal airway infection may also depict the tree-in-bud sign in association with other findings. Examples include cystic fibrosis, tuberculosis, postinfectious bronchiectasis and allergic bronchopulmonary mycoses.[41] Table 25.5 summarizes disorders associated with tree-in-bud opacities with individual characteristic features.

TABLE 25.5: Characteristic features of bronchiolar diseases with tree-in-but opacities

	Characteristic clinical features	*Causes and/or associated conditions*	*HRCT features*	*Histophathologic features*
Infection	Wheezing with concomitant signs of respiratory tract infection	Viral, bacterial, parasitic, mycobacterial, fungal	Tree-in-bud pattern, centrilobular nodules, dense consolidation	Acute and chronic inflammation of small bronchioles with epithelial necrosis and sloughing
Immunologic disorders (allergic bronchopulmonary aspergillosis)	Cough, fever, wheezing; recurrent episodes of bronchial obstruction	Asthma	Tree-in-bud pattern, central bronchiectasis, mucoid impaction, upper lobe predominance	Mucoid impaction of bronchi, eosinophilic infiltration, bronchocentric granulomatosis
Congenital disorders (CF, dyskinetic cilia syndrome)	Recurrent purulent cough, airway hyperactivity	Genetic predisposition, multisystem disease	Tree-in-bud pattern, bronchial wall thickening, bronchiectasis, bronchiolectasis	Cellular infiltration
Neoplasms	Symptoms and signs of upper respirtory tract obstruction (hoarseness, stridor)	Juvenile laryngotracheo-bronchial papillomatosis	Tree-in-bud pattern, multiple solid or cystic nodules	Varies from multiple clusters of squamous cells within alveoli to large cavitary lesions
Diffuse aspiration bronchiolitis	Nonspecific	Elderly, bed bound	Tree-in-bud pattern, centrilobular nodules	Foreign body giant cell reaction
Idiopathic diffuse panbronchiolitis	Mainly in Japanese adults; subacute onset of cough, dyspnea	Associated sinusitis, HLABw54 antigen	Tree-in-bud pattern, thickened ecstatic bronchi, centrilobular nodules	Infiltration of lymphocytes, plasma cells and foamy macrophages at the level of respiratory bronchiole

CF = cystic fibrosis; HRCT = high-resolution CT.

(Devakonda A, Raoof S, Sung A, Travis WD, Naidich D. Bronchiolar disorders. A clinical-radiological diagnostic algorithm Chest 2010; 137; 938-51.)

Poorly Defined Centrilobular Nodules and Bronchiolar Disease

Compared to infectious bronchiolitis, the distinguishing finding of this group of bronchiolar disease is the presence of ill-defined centrilobular nodules in the absence of a tree-in-bud picture. A variety of diseases with peribronchiolar inflammation without the tree-in-bud pattern have been described. This includes subacute hypersensitivity pneumonitis, lymphocytic interstitial pneumonitis, follicular bronchiolitis, Respiratory Bronchiolitis-Interstitial Lung Disease (RBILD) and mineral dust-induced bronchiolitis.[37]

Focal Ground Glass Attenuation or Consolidation and Bronchiolar Disease

This presentation of focal ground glass attenuation is most characteristic of Cryptogenic Organizing Pneumonia (COP) or Bronchiolitis Obliterans with Organizing Pneumonia (BOOP).[42] Patients usually complain of symptoms of nonproductive cough for several months, low-grade fever and increasing dyspnea. The most common radiologic finding on HRCT in COP is patchy bilateral consolidation commonly with peribronchial and subpleural distribution.[43] Small, poorly formed peribronchiolar nodules and irregular linear opacities are seen in a smaller percentage of patients. However, the tree-in-bud pattern is clearly uncommon. Areas of ground glass consolidation may be seen in immunocompromised patients with COP.

Decreased Parenchymal Attenuation and Bronchiolar Disease

This category includes patients with constrictive or obstructive bronchiolitis. Conditions associated with

Flow chart 25.2: A stepwise approach to bronchiolar disease. History, physical findings, evidence of hyperinflation on chest radiograph or airflow obstruction on pulmonary function testing suggestive of bronchiolar disease, should trigger a request for obtaining an HRCT scan of the chest performed at the end of inspiration and expiration. A HRCT scan of the chest further classifies bronchiolar diseases. The presence of a tree-in-bud pattern largely suggests either an infectious bronchiolitis, if a focal distribution is noted, or diffuse panbronchiolitis or congenital disease related bronchiolitis, if a diffuse pattern is noted. If centrilobular nodules are predominantly seen, then RB-ILD should be suspected in a smoker or HP in a non-smoker. Mosaic attenuation suggests either a constrictive bronchiolitis or obliterative bronchiolitis. Histology is ultimately required for the final confirmation

ABPM = allergic bronchopulmonary mycosis; BAC = bronchoalveolar cell carcinoma; CF = cystic fibrosis; CHF = congestive heart failure; HP = hypersensitivity pneumonitis; PFT = pulmonary function test; PLCH = pulmonary Langerhans cell histiocytosis; RB-ILD = respiratory bronchiolitis-inetrstitial lung disease; TBBX = transbronchial biopsy

(Devakonda A, Raoof S, Sung A, Travis WD, Naidich D. Bronchiolar disorders. A clinical-radiological diagnostic algorithm Chest 2010;137;938-951)

obstructive bronchiolitis include lung transplant, chronic graft-versus-host disease from allogeneic bone marrow transplant and collagen vascular disease.[44] Clinical symptoms are usually mild, but severe respiratory compromise may result from progressive airway obstruction. Mosaic attenuation is commonly seen in obstructive bronchiolitis with the presence of bronchial dilatation, peribronchial thickening and evidence of air trapping on expiratory HRCT.[45]

Bronchiolar disease should be approached using systematic method as illustrated in Flow chart 25.2.

PARENCHYMAL DISEASES

Solitary Pulmonary Nodule (SPN)

The evaluation of focal lung disease poses a challenge in the diagnosis of pulmonary disorders. There is a lack of consensus leading to several controversies in the definition, assessment and diagnostic techniques, including the imaging and mode of pathologic confirmation of focal lung diseases. For the purpose of this chapter, we will define a solitary pulmonary nodule as a single, rounded lesion in the lung parenchyma, which is not associated with atelectasis or pneumonia. Solitary pulmonary nodules are a common, incidental finding on CT imaging. Characterization of the secondary pulmonary nodule is of utmost importance and may aid in narrowing the differential diagnosis, preventing further unnecessary procedures or missing localized malignancy (Also see Chapter 120A).

Size

The size of a solitary pulmonary nodule on CT has been shown to directly influence the probability of malignancy.[46] Nodules larger than 3 cm are more apt to being malignant. However, smaller lesions, even of less than 1 cm in size have been shown to be malignant in several studies.[47]

Location

Primary lung cancers have been shown to be more commonly located in the upper lobes, particularly on the right side.[48] SPNs have also been reported to be identified in the lung periphery, rather than the medial third of the lung. Metastatic lesions are predisposed to be subpleural in location and are predominantly seen in the lower lobes.[49] Nevertheless, several other lesions, such as lymph nodes are also seen in the subpleural distribution.[50]

Margin and Contour

Benign nodules tend to demonstrate a round, smooth contour with a sharply defined margin. Malignant lesions are more likely to exhibit an irregular lobulated or ragged shape and a vague, irregular or spiculated edge.[51] However, malignant lesions have been reported to demonstrate a smooth appearance and benign condition have shown lobulated or spiculated contours.[52]

Halo Sign

A halo sign is defined as a distinct nodule surrounded by a circular margin of ground glass attenuation.[53] This sign has been most commonly associated with the early course of invasive pulmonary aspergillosis in the correct clinical context. It has however also been reported in Wegener's granulomatosis, Kaposi's sarcoma and bronchoalveolar carcinoma.

Bronchus Sign

The identification of an air bronchogram on CT is of important value. Although non-specific, the present bronchial lumen surrounded by a pulmonary lesion is likely to be malignant. Airways related to lung cancer tend to be abnormal, appearing ecstatic or tortuous.[54]

Cavitation

Several etiologies may result in cysts and cavities, including septic emboli, vasculidities and tumors. CT helps in characterizing cysts and cavities, allowing for the closer evaluation of wall thickness and intracavitary findings such as air-fluid levels. Thin walled cavities tend to be benign, whereas thick walled cavities may be of uncertain etiology.[55]

Feeding Vessel Sign

A focal lesion with an adjacent vessel, known as a feeding vessel sign or vessel-mass sign, has been described in various conditions such as arteriovenous malformations, metastasis or infarcts.[56] Although, it is not reported to be a common finding, a feeding vessel sign is helpful in distinguishing hematogenous metastasis from either primary or granulomatous lesions. It is also useful in diagnosing septic emboli and pulmonary vasculitis is the appropriate clinical situation.

Growth Rates

One of the most important radiographic factors allowing for distinction between benign and malignant disease is the growth rate of the SPN. It is therefore paramount to review prior chest imaging in the evaluation of a SPN. The absence of detectable growth over a two-year period is highly suggestive of a benign etiology.[57] The doubling time of a SPN is the time it takes to double the size, can be determined using the changes in diameter. A 26% increase in diameter will result in a doubling volume of the SPN. A majority of malignant SPNs have a doubling time of 20–400 days.

Calcification

The radiographic presence of calcification reliably suggests that a pulmonary lesion is benign.[58] Furthermore, four patterns of benign calcification have been studied: Laminated and concentric; dense central core; diffuse; and solid and punctuate. In malignant processes, calcifications classically appear speckled or eccentric and usually within large central lesions.[59]

Fat

The appearance of fat is suggestive of two key conditions: Hamartoma or exogenous lipoid pneumonia. A hamartoma is a benign condition, which contains connective tissue, cartilage, smooth muscle, bone and variable amount of fat and represents the third most common cause of a solitary pulmonary nodule.[60] They can be diagnosed by CT as lesions containing fat or fat and calcification, as well as have an even contour with a sharp circumference.[46]

Contrast Enhancement

Due to the fundamental differences in vascularity of focal benign versus malignant lesions, the phenomenon of pulmonary enhancement has been a valuable tool in differentiating the two processes.[61] Malignant lesions are more prone to enhancement following the injection of contrast material. It has been reported that malignant lesion may enhance by greater than 15–20 Hounsfield units.[62]

Diffuse Diseases

Diffuse parenchymal lung diseases are compiled of chronic and acute infiltrative lung diseases and emphysema. These conditions in addition to being diffuse in nature often have patchy or focal distribution. Suggestive findings that indicate parenchymal irregularity in diffuse lung disease include linear and reticular opacities, nodular opacities, and increased attenuation seen as consolidation or ground glass opacities and decreased attenuation seen in emphysema and cystic diseases.

Several acute and chronic pulmonary conditions result in diffuse infiltration of the lungs. They can be classified based on the predominant radiographic pattern on CT (Table 25.6). There are seven distinct histologic types of idiopathic interstitial pneumonias. They include Usual Interstitial Pneumonia/Idiopathic Pulmonary Fibrosis (UIP/IPF), Nonspecific Interstitial Pneumonia (NSIP), Desquamative Interstitial Pneumonia (DIP), respiratory bronchiolitis interstitial pneumonia, Acute Interstitial Pneumonia (AIP), COP/BOOP, and Lymphocytic Interstitial Pneumonia (LIP).[63] High resolution computed tomography evaluation may avoid the necessity for tissue diagnosis and may limit the differential diagnosis in some cases.

Reticular Pattern

Idiopathic pulmonary fibrosis: Idiopathic pulmonary fibrosis has characteristic HRCT findings that can lead to its diagnosis with a high degree of certainty.[64] In the early phase of IPF patchy, the peripheral distribution of ground glass opacities is seen with the areas of normal lung intermingled between the areas of involved lung.

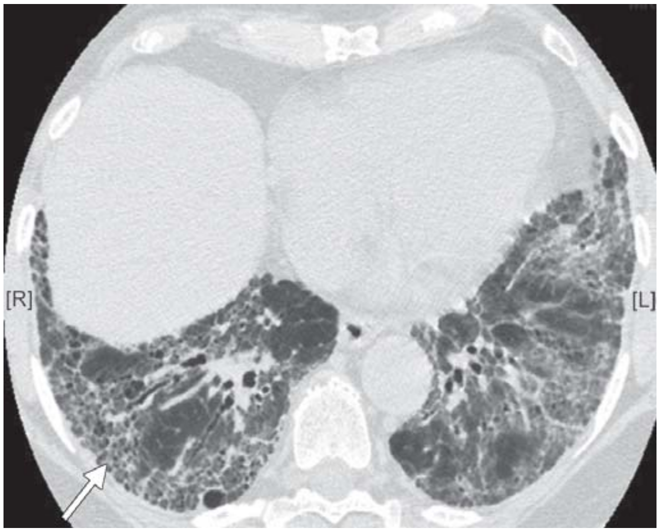

Fig. 25.35: HRCT showing cuts through the lower lobes showing reticular changes including honeycombing, traction bronchiectasis and architectural distortion

The main pattern of abnormality seen on HRCT in a later stage in patients with IPF include intralobular linear opacities, which correspond to histologic areas of fibrosis, a fine reticular pattern, most pronounced at the lung bases and in the subpleural regions and irregular interfaces between the lung and pulmonary vessels, bronchi and pleural surfaces[65] (Fig. 25.35). This progression of fibrosis ultimately results in the dilatation and tortuosity of bronchi and bronchioles, referred to as traction bronchiectasis. The end stage of IPF is illustrated by honeycombing, noted most severely at the lung bases and in subpleural sites.[66] IPF is classically represented as a patchy distributed disease, with spatial and temporal heterogeneity. This refers to the areas of normal lung, reticular changes or honeycombing seen in the same patient within the same lung section.

Nonspecific interstitial pneumonitis: There are two forms of NSIP, which can occur: Cellular or a fibrotic NSIP. HRCT features of NSIP include ground-glass attenuation in a diffuse or patchy distribution with reticular opacities and traction bronchiectasis.[67] In cellular NSIP, there is a prevalence of ground glass attenuation (Fig. 25.36) and in fibrotic NSIP more reticular changes are noticeable (Fig. 25.37). Findings of honeycombing are seldom noted. NSIP, unlike UIP, displays temporal and spatial homogeneity, where there is a uniform pattern of HRCT changes within the same lung segment.

Collagen vascular disease: HRCT features similar to IPF may be seen in various collagen vascular diseases such as

TABLE 25.6: Radiographic patterns in diffuse lung disease

Pattern of opacities		
Consolidation		
	Acute:	Infection, acute respiratory distress syndrome, hemorrhage, aspiration, acute interstitial pneumonia, cyptogenic organizing pneumonia [also called idiopathic bronchiolitis obliterans with organizing pneumonia (BOOP)].
	Chronic:	Chronic infection (tuberculosis fungal), chronic eosinophilic pneumonia, crytogenic organizing pneumonia, lymphoproliferative disease bronchioloalveolar carcinoma, pulmonary alveolar proteinosis, sarciodosis (rarely)
Linear or reticular opacities		
	Acute:	Infections (viral mycoplasma), pulmonary edema
	Chronic:	Idiopathic pulmonary fibrosis (IPF) or usual interstitial pneumonia, connective tissue diseases-associated pulmonary fibrosis, asbestosis, sarcoidosis, hypersensitivity pneumonia, drug-induced lung disease
Small nodules (round opacities <1 cm in diameter)		
	Acute:	Infections (disseminated tuberculous, fungal or viral infections), hypersensitivity pneumonitis (poorly circumscribed centrilobular)
	Chronic:	Sarcoidosis, hypersensitivity pneumonitis, silicosis, coal worker's pneumoconiosis, respiratory bronchiolitis metastases, alveolar microlithiasis
Cystic airspaces		
	Acute:	*Pneumocystis carinii* pneumonia, septic embolism.
	Chronic:	Pulmonary Langerhans cell histiocytosis, pulmonary lymphangioleiomyomatosis, honeycomb lung causes by IPF or other disorders, metastatic disease (rare)
Ground-glass opacities		
	Acute:	Infection (*P. carinii*, cytomegalovirus), pulmonary edema hemorrhage, hypersensitivity pneumonitis, acute inhalational exposures, durg-induced lung disease acute interstitial pneumonia
	Chronic:	Nonspecific interstitial pneumonia (idiopathic or related to underlying disease, e.g. connective tissue disease), respiratory bronchiolitis-associated interstitial lung disease, desquamative interstitial pneumonia, drug induced lung disease, pulmonary alveolar proteinosis
Thickened interlobular septa		
	Acute:	Pulmonary edema
	Chronic:	Lymphangitic carcinomatosis, pulmonary alveolar proteinosis, sarcoidosis, pulmonary veno-occlusive disease
Distribution		
Upper lung predominance: Pulmonary Langerhans cell histiocytosis, silicosis, coal worker's pneumoconiosis, carmustine-related pulmonary fibrosis, reactivation tuberculosis, *P. carinii* pneumonia on pentamidine prophylasis		
Lower lung predominance: IPF, pulmonary fibrosis associated with connective tissue diseases, asbestosis, chronic aspiration		
Central (perihilar) predominance: Sarcoidosis, beryllosis		
Peripheral predominance: IPF, chronic eosinophilic pneumonias, cryptogenic organizing pneumonia (or idiopathic BOOP)		
Associated findings		
Pleural effusion or thickening: Pulmonary edema, connective tissue diseases, asbestosis, lymphangitic carcinomatosis lymphoma, lymphangioleiomyomatosis, drug-induced diseases.		
Lymphadenopathy: Infections sarcoidosis silicosis (sarcoidosis and silicosis may be associated with lymph nodes that are calcified in an eggshell patterns), berylliosis, lymphangitic carcinomatosis, lymphoma, lymphocytic interstitial pneumonia.		

(Ryu JH, Olson EJ, Midthun DE, Swensen SJ. Diagnostic approach to the patient with diffuse lung disease Mayo Clin Proc. 2002;77: 1221-1227)

rheumatoid arthritis, scleroderma, mixed connective tissue disease, polymyositis and systemic lupus erythematous.[68] Rheumatoid arthritis may result in fibrosis in a small percentage of patients, with a similar lower lung zone distribution as IPF. More commonly seen are pleural manifestations, but other findings, such as bronchiectasis or rheumatoid nodules can occur.[69] Scleroderma may result in fibrosis with fine reticulation, as well as ground glass attenuation, honeycombing or pleural thickening.[70]

Asbestosis: Asbestosis leads to predominantly basilar and dorsal lung parenchymal fibrosis. Other characteristic findings include: Peribronchiolar fibrosis that forms

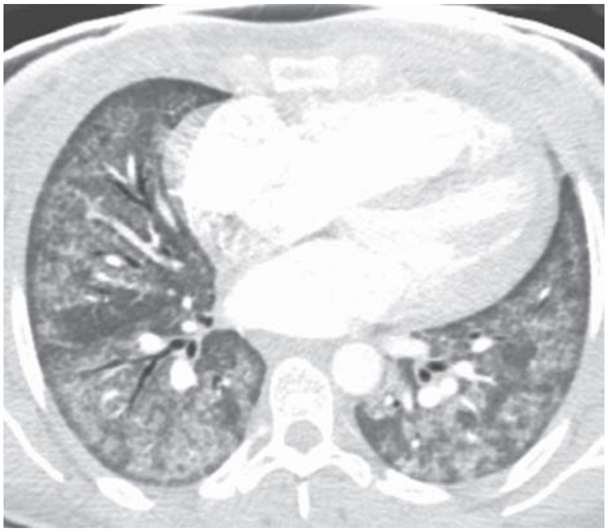

Fig. 25.36: CT chest features of NSIP with diffuse, bilateral ground glass attenuation at the lower lung zones. Note the absence of honeycombing

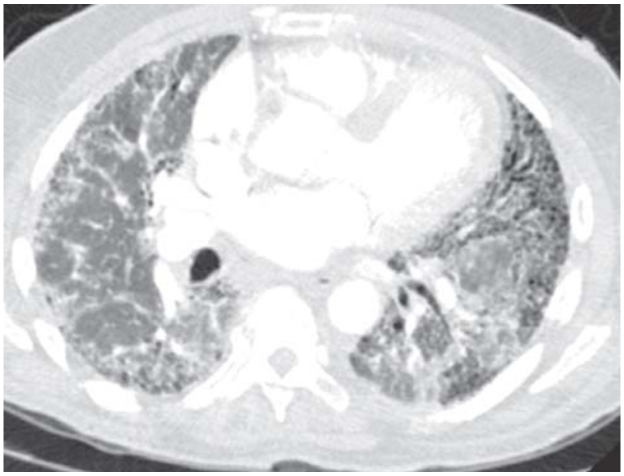

Fig. 25.37: CT Chest through the middle lung zones in a patient with NSIP

centrilobular nodules, intralobular and interlobular septal fibrosis that forms subpleural short lines, coarse parenchymal bands, and subpleural curvilinear bands that parallel the pleura and represent fibrotic bridging from one centrilobular region to the next.[71] Coarse honeycombing can be seen in advanced stages. Coexistent pleural plaques are frequently identified, particularly in patients with curvilinear subpleural lines.[72]

Nodular Pattern

The differential diagnosis of nodular disease includes an extensive list of benign and malignant processes. Nodular disease can be further analyzed based on the predominant distribution of nodules: Perilymphatic; centrilobular or random distribution[10] (Flow chart 25.3).

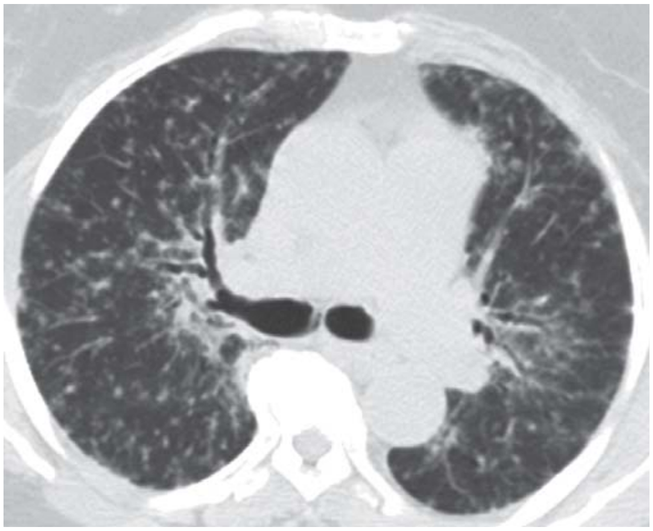

Fig. 25.38: HRCT at the level of the right upper lobe bronchus showing small nodules and nodular thickening along the bronchovascular bundles, interlobular septa, interlobular fissures, and subpleural lung regions in a patient with sarcoidosis

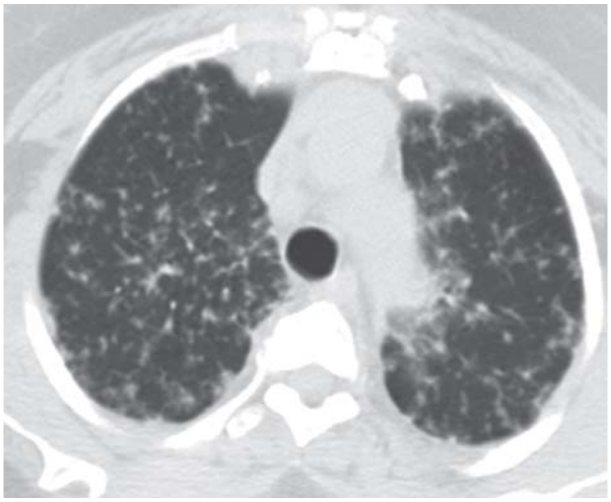

Fig. 25.39: HRCT through the upper lung zones showing multiple small nodules throughout with nodules seen along the subpleural regions and along the interlobular septa and interlobular fissures

Perilymphatic distribution: This includes the following diseases:

Sarcoidosis: The characteristic HRCT finding of sarcoidosis include small nodules and nodular thickening along the bronchovascular bundles, interlobular septa, interlobular fissures and subpleural lung regions[73] (Figs 25.38 and 25.39). The bronchovascular thickening is

Raoof S, Amchentsev A, Vlahos I, et al. Pictorial essay: mulitinodular disease: a high-resolution CT scan diagnostic algorithm. Chest. 2006; 129(3):805-15.

most pronounced at the hila. The nodules appear irregular and represent the coalescence of microscopic granulomas. As fibrosis develops, reticular changes, such as intralobular septal thickening, occur and ultimately lead to architectural distortion, loss of lung volume and traction bronchiectasis.[74] Honeycombing may be seen with sarcoidosis, although it is usually mild and involves primarily the upper and middle lung zones, with relative sparing of the lung bases.[75] Hilar and mediastinal lymphadenopathy is another feature of sarcoidosis seen on CT, with calcification noted in longstanding disease.[76]

Silicosis/coal workers pneumoconiosis: The most characteristic findings in silicosis and coal worker's pneumoconiosis are small nodules predominantly seen in the posterior aspects of the upper lung zones. These nodules vary in size, may be calcified and are distributed largely in the centrilobular pattern.[77] Progressive massive fibrosis is seen as a conglomerate of nodules with an irregular margin, often resulting in architectural distortion.

Lymphangitic carcinomatosis: Pulmonary lymphangitic carcinomatosis refers to the lymphangitic or hematogenous spread of tumor to the lungs resulting in the infiltration and thickening of the interlobular septa, subpleural interstitium and bronchovascular bundles and preservation of the normal lung architecture[78] (Fig. 25.40). The thickening of this structure may be

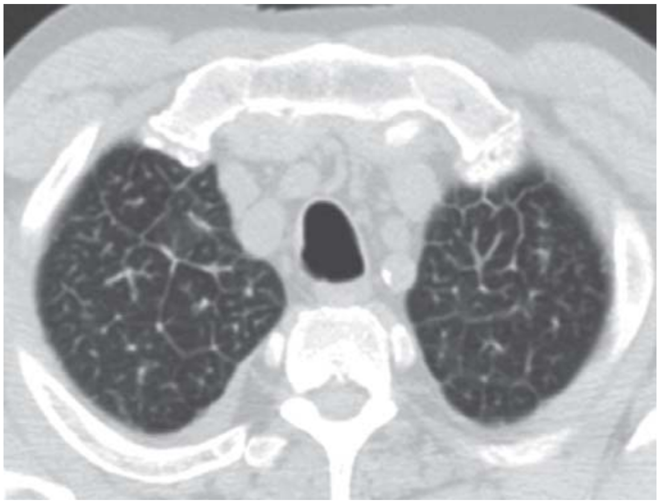

Fig. 25.40: HRCT through upper lobes demonstrating intralobar septal thickening in a patient with lymphangitis carcinomatosis

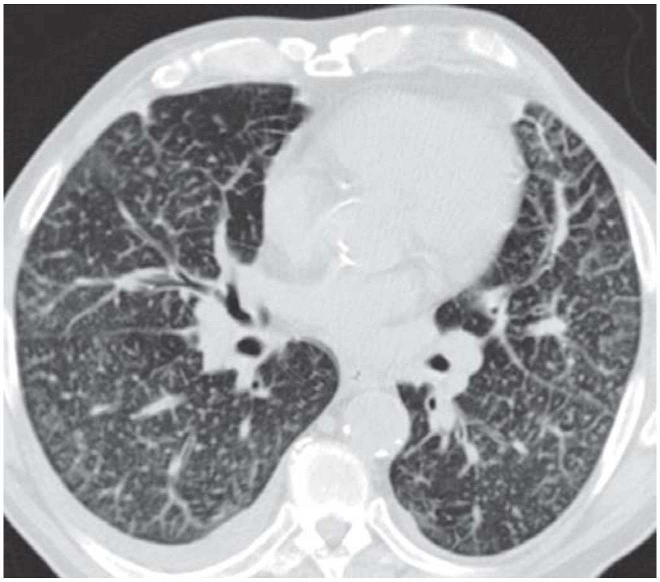

Fig. 25.41: HRCT at the level of the lower lobe bronchi showing a fine reticular pattern from interlobular septal thickening and multiple tiny nodules in a patient with lymphangitic carcinomatosis. Note the extension of the irregular interlobular septal thickening to the pleural surface

smooth or have a nodular appearance and may be diffuse and bilateral or focal and unilateral in distribution (Fig. 25.41). The most common primary malignancies resulting in lymphangitic carcinomatosis are adenocarcinoma of the breast, lung, gastrointestinal tract and prostate.

Centrilobular distribution (ground-glass nodules): This section includes the following diseases:

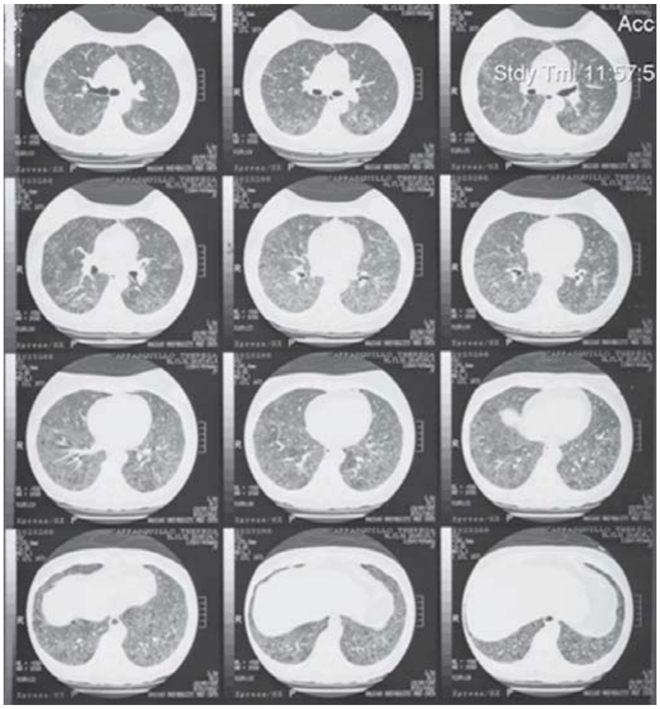

Fig. 25.42: CT chest representing hypersensitivity pneumonitis. Numerous centrilobular nodule which are poorly defined and shown to extend to the periphery are illustrated

Hypersensitivity pneumonitis: Hypersensitivity pneumonitis, also known as extrinsic alveolitis represents a type 3 allergic reaction or immune complex disease. HRCT is most useful in diagnosing subacute hypersensitivity pneumonitis, where it displays diffuse or patchy ground-glass opacification with lobular sparing, lobular air-trapping and centrilobular poorly defined airspace nodules.[79] The ground-glass attenuation is noted predominantly in the middle and lower lung zones and may be present in combination with mosaic attenuation (Fig. 25.42). In chronic hypersensitivity pneumonitis, fibrosis, represented by a reticular pattern, architectural distortion and ultimately honeycombing is seen with relative basilar sparing.[80]

Lymphocytic interstitial pneumonitis: Lymphocytic interstitial pneumonitis can be seen in patients with Sjögren's syndrome and is seen commonly in children with acquired immune deficiency syndrome. Dense infiltration of monoclonal or polyclonal T lymphocytes occurs in the interstitium. It can lead to lymphoma of the lung parenchyma. The characteristic features on HRCT include ground-glass opacities, reticular opacities and perivascular cysts[81] (Figs 25.43 and 25.44).

Centrilobular distribution (tree-in-bud): This section includes the following diseases:

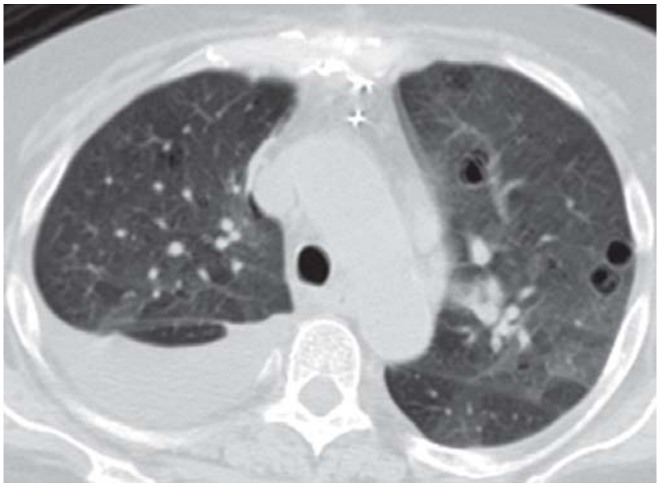

Fig. 25.43: CT chest through the upper lobes demonstrating cystic changes in a patient with LIP. Also noted is a pleural effusion on the right

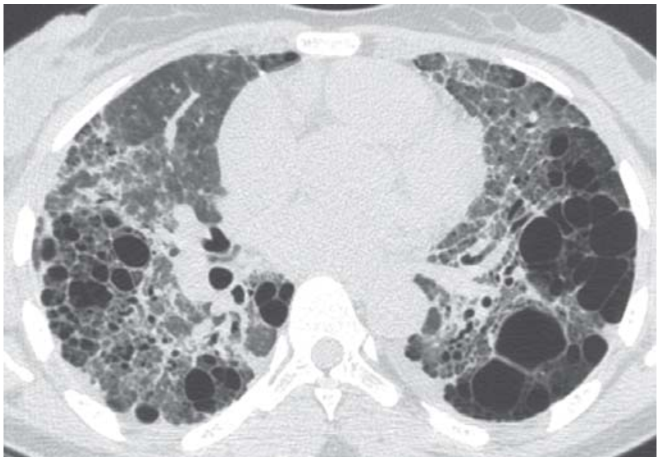

Fig. 25.44: CT Chest through the lower lungs demonstrating cystic changes in a patient with lymphocytic interstitial pneumonitis

Panbronchiolitis: Panbronchiolitis is a form of diffuse bronchiolitis found in Asia, especially Japan and Korea.[82] The characteristic CT features of diffuse tree-in bud pattern are seen mainly affecting the lower lung zones, with complete resolution after macrolide therapy. Typically seen are centrilobular nodular and linear opacities corresponding to thickened and dilated bronchiolar walls with intraluminal mucous plugs, mosaic attenuation, as a result of peripheral air trapping and bronchiectasis, especially in advanced disease.[83]

Infectious etiology: The tree-in-bud pattern is frequently seen in several airway infections from viral etiologies; bacterial infections, such as MTB or MAI; and fungal etiologies such as Allergic Bronchopulmonary Mycosis (ABPM).[41]

Random distribution: This section includes the following disease:

Hematogenous metastasis: Hematogenous tumor metastasis most commonly results in localized tumor nodules, rather than lymphatic infiltration. Multiple, large, well-defined nodules involving the lower lung zones are seen in a randomly distributed fashion.[84]

Pulmonary Opacities

Ground-glass opacities: This section includes the following diseases:

Desquamative interstitial pneumonitis/respiratory bronchiolitis interstitial lung disease: These diseases are exclusively found in smokers. The major HRCT finding in patients with respiratory bronchiolitis is the presence of ill-defined, centrilobular ground-glass nodules, primarily in the upper lobes. DIP may be distinguished from RBILD by the presence of ground glass attenuation, which is predominantly found in the middle and lower lung zones[85] (Fig. 25.45). Mild fibrosis is indicated by irregular linear opacities, architectural distortion and honeycombing may be seen in the subpleural and lower lung regions. DIP and RBILD are likely to be related or even part of the same pathologic process, differing only in the severity, location and extent of the abnormality.

Acute interstitial pneumonitis: Acute interstitial pneumonitis is also known as Hamman-Rich syndrome and is characterized by an acute onset and rapid progression. HRCT findings are of diffuse ground-glass attenuation and

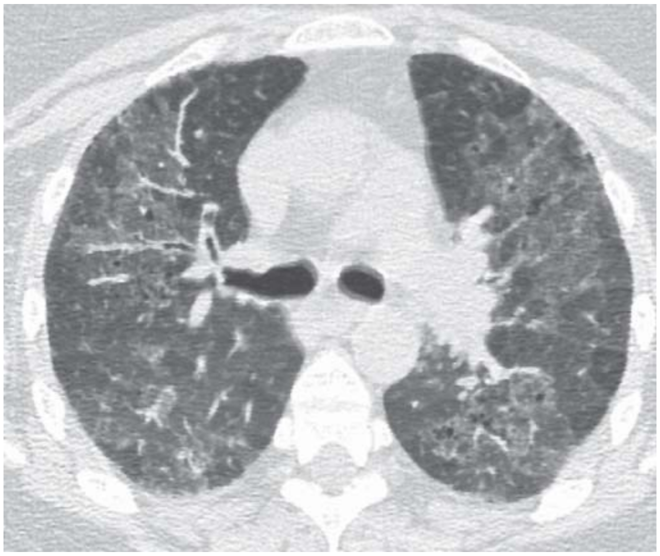

Fig. 25.45: CT chest through the upper lobes in a patient with desquamative interstitial pneumonitis showing a diffuse ground-glass attenuation

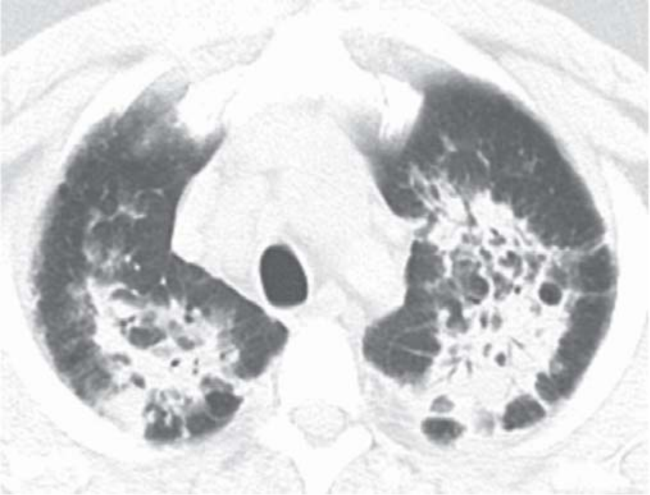

Fig. 25.46: CT chest showing bilateral dense consolidation in the upper lobes in cryptogenic organizing pneumonia

consolidation with abnormalities suggestive of fibrosis such as traction bronchiectasis.[86]

Pulmonary alveolar proteinosis: Pulmonary Alveolar Proteinosis (PAP) results from the ineffective clearance of surfactant from alveoli. The predominant HRCT features of PAP consist of the bilateral areas of ground-glass opacification with smoothly thickened interlobular septal lines.[87] This pattern is also called “crazy paving.” There may be lobular or geographic sparing. Other features seen on HRCT include poorly defined nodular opacities and consolidation.[88]

Consolidation

BOOP/COP: HRCT typically shows the peribronchial and peripheral areas of consolidation[89] (Figs 25.46 and 25.47). Another suggestive finding is the presence of rings or crescents of consolidation surrounding ground-glass opacities, which has been called a reverse halo sign.[90]

Bronchoalveolar Carcinoma (BAC): Bronchoalveolar carcinoma may present with three distinct patterns,[91] as well as as a small solitary nodule, which has a characteristic ground-glass appearance on CT, suggestive of a good prognosis. It may also present as lobar consolidation resembling bacterial pneumonia, where the CT features typically show air bronchograms. BAC may also be represented as multifocal pulmonary nodules.

Cystic Diseases

There are many pulmonary conditions that may result in cystic changes on CT. Flow chart 25.4 illustrates the classification of multiple hypolucent lesions according to the distributive pattern.

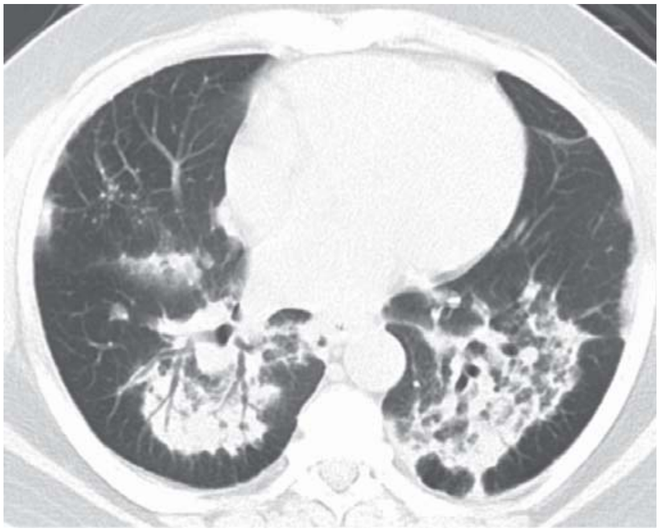

Fig. 25.47: CT chest through the lung bases showing dense bilateral consolidation with air bronchograms in a patient with cryptogenic organizing pneumonia

Lymphangioleiomyomatosis (LAM): LAM affects the women of reproductive age and results from a smooth muscle proliferation within the pulmonary interstitium causing thickening of the walls of the lymphatics, blood vessels and bronchioles. Patients are present with spontaneous pneumothorax, chylothorax, hemoptysis and marked hyperexpansion of the lungs. HRCT demonstrates multiple thin walled cysts diffusely throughout the lung[92] (Fig. 25.48). The cysts are rounded

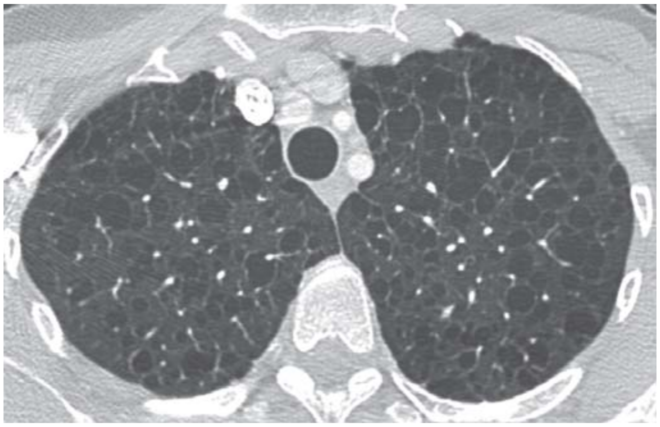

Fig. 25.48: CT chest through the upper lobes showing diffuse cystic changes in a patient with lymphangioleiomyomatosis. The cysts are evenly distributed and have thin, definable walls. Note the absence of nodules

Flow chart 25.4: Multiple lucent lesions are classified according to their distribution pattern as either focal or diffuse. The focal lucencies can further be distinguished into upper lobe, lower lobe or random distribution. Examples of diffuse lucent lesions include panacinar emphysema, LAM, LIP or congenital disease related diffuse bronchiectasis. Examples of focal upper lung lucent lesions include centrilobular or paraseptal emphysema, LCH with presence of small nodules and infectious etiologies. Focal lower lung lucencies are usually seen in interstitial lung diseases, such as UIP, DIP and RBILD as cystic changes with ground glass opacities also seen in DIP and RBILD. Randomly distributed focal lucencies may be seen in a braod group of conditions, such as rheumatoid arthritis, necrotizing pneumonia and cavitating infarctions after a pulmonary embolism

Hydatid disease
RA. ANCA-associated granulomatous vasculitis
Pulmonary infarction with cavitation after a pulmonary embolism
Pulmonary contusion wtih cavity formation
Panacinar emphysema (No perceptible cyst wall, GGO-), e.g. A1AT deficiency
CF (Some predilection to upper lobes)
Honeycomb lung (advanced IPF, CTD-related pulomonary fibrosis, asbestosis)
Chronic hypersensitivity pneumonitis
LAM and tuberous sclerosis
Malignancy (located in the outer third of the lung), e.g. head and neck, cervical, bladder, esophageal, squamous lung cancer, BAC, melanoma, lymphoma
Infections, e.g. staphlococcus, klebsiella, pseudomonas, aspergillus, mucormycosis, cocci, crypto, nocardia, tuberculosis
Septic emboli (peripheral distribution)
LIP (Interlobular septal thickening, thickening of bronchovascular bundles, scattered cysts)
Bronchiectasis, diffuse,
e.g. Birt-Hogg-Dube (skin and renal lesions) Young's syndrom
Metastatic disease (rare)

LCH: Langerhans cell histiocytosis; TB: tuberculosis; PCP: *Pneumocystic jiroveci*; UIP: usual interstitial pneumonitis, DIP: desquamative interstitial pneumonitis; RBILD: respiratory bronchiolitis-inetrstitial lung disease; RA: rheumatoid arthritis; A1AT: alpha-1-antitrypsin; CF: cystic fibrosis; IFP: idiopathic pulmonary fibrosis; CTD: connective tissue disease; LAM: lymphangioleiomyomatosis; BAC: bronchoalveolar carcinoma; LIP: lymphocytic interstitial pneumonitis

and may vary in size, but bizarre-shaped cysts as those seen in Langerhans cell histiocytosis, are unlikely (Fig. 25.49).

Langerhans cell histiocytosis: Langerhans cell histiocytosis (LCH) also known as eosinophilic granuloma or histiocytosis X is recognized on CT by the presence of cysts showing an upper lobe predominance, especially in the early stages. The initial changes include small nodular opacities with sharply defined or stellate centrilobular nodules seen on HRCT. Multiple thin-walled cysts of varying sizes are usually present in scattered form throughout the upper and middle lung zones with the relative sparing of the bases. The cysts have bizarre, irregular shapes, which can appear in combination with nodules in the intermediate stages of the disease[93] (Fig. 25.50).

Pneumocystis pneumonia: Pneumocystis Jiroveci Pneumonia (PJP, previously called pneumocystis carinii pneumonia)

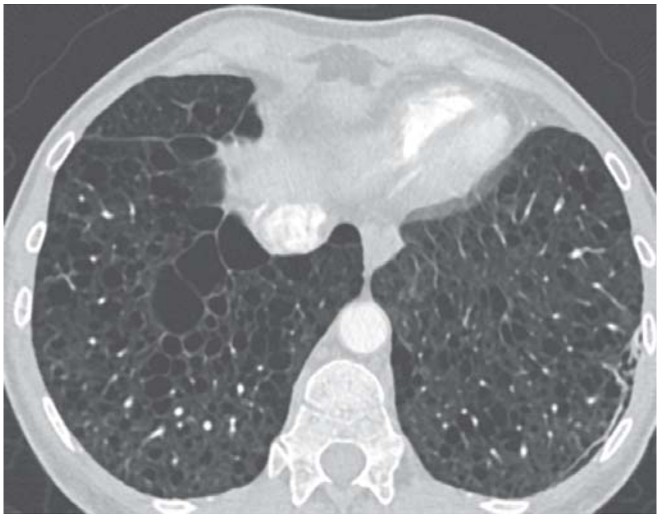

Fig. 25.49: CT chest in a patient with lymphangioleiomyomatosis showing well defined, multiple cysts with uniform distribution at the lung bases

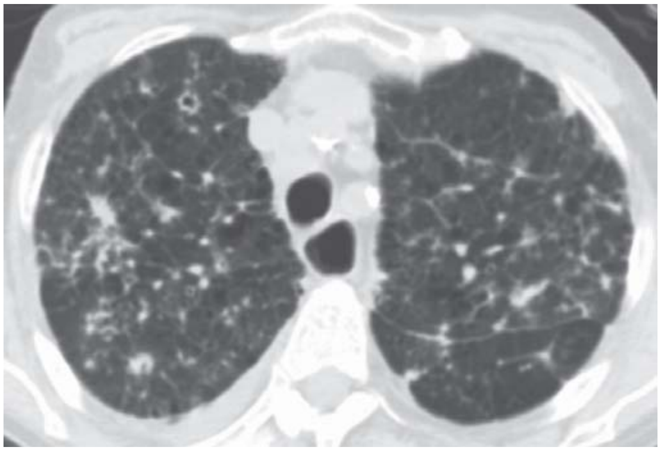

Fig. 25.50: HRCT through the upper lobes in a patient with langerhans cell histiocytosis. There are nodules present with irregular cysts with thin and thick walls

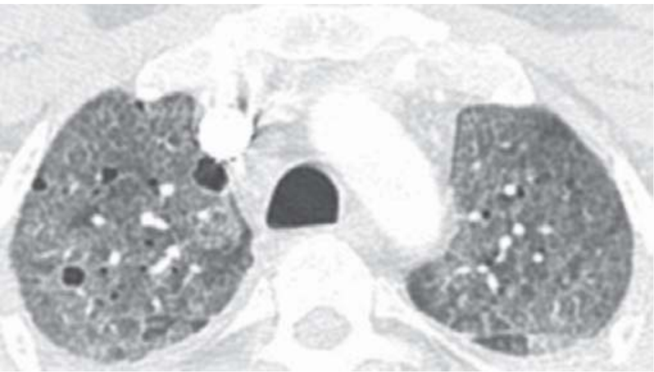

Fig. 25.51: A classic CT chest representation of diffuse ground glass attenuation in a patient with *pneumocystic carinii* pneumonia

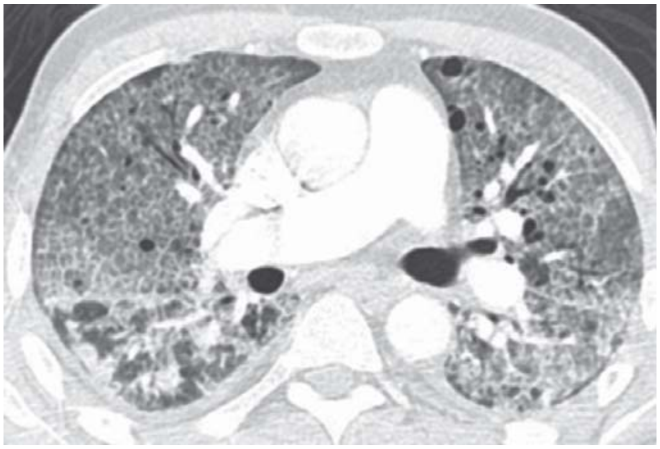

Fig. 25.52: CT chest showing a diffuse ground glass pattern with a crazy paving appearance in a patient with *pneumocystic carinii* pneumonia

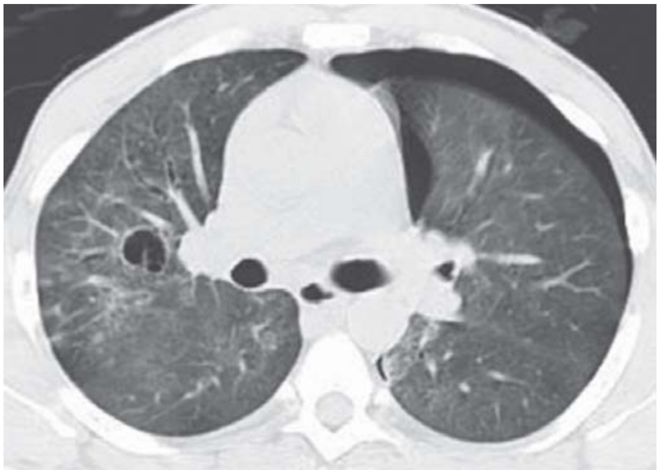

Fig. 25.53: CT Chest in a patient with *pneumocystic carinii* pneumonia with evidence of pneumothorax and bilateral diffuse haziness

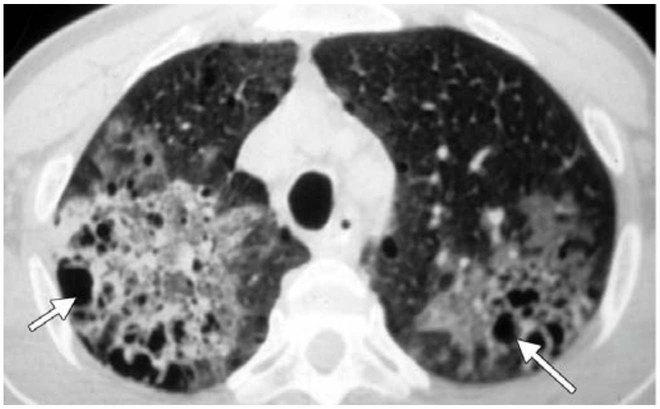

Fig. 25.54: HRCT through the upper lung zones showing a dense opacity in the right upper lobe, ground glass opacities in the left upper lobe, small and large (arrows) cysts in a patient with *Pneumocystic jiroveci* pneumonia

is one of the most common pulmonary infections in patients with AIDS. The HRCT findings of PJP have been well studied. These findings consist of bilateral ground-glass attenuation, which appear consolidated with severe disease and a distinct mosaic pattern with the areas of normal lung interspersed between the areas of ground-glass opacities[94] (Figs 25.51 and 25.52). Other associated findings include pneumothoraces or cystic lung changes (Figs 25.53 and 25.54).

MEDIASTINAL DISEASES

The mediastinum is bounded laterally by the lungs, anteriorly by the sternum, and posteriorly by the vertebral bodies. Several focal and diffuse conditions may occur within the mediastinum. The mediastinum can be divided into compartments based on CT landmarks to facilitate the differential diagnosis of various findings. These include the anterior mediastinum, which includes the retrosternal clear space and the cardiophrenic angle; the middle mediastinum, which includes the retrosternal clear space, subcarinal region and retrocardiac clear space; and the posterior mediastinum. It should be pointed out that there are no physical boundaries between compartments that may limit any mediastinal disease.

The Retrosternal Clear Space

This region is bordered anteriorly by the sternum and posteriorly by the aorta and the great vessels. The normal structures located in this region include the thymus gland, lymph nodes and fat. Abnormalities involving the retrosternal clear space include thymoma, thymic cyst, lymphoma, teratoma, aortic aneurysm or lipoma. Thymomas represent a majority of anterior mediastinal lesions in adults. The CT appearance of a thymoma shows a homogenous soft-tissue rounded or lobulated mass, which is sharply demarcated and does not conform to the normal shape of the thymus.[95] Thymic cysts appear thin walled, with air fluid levels on CT (Fig. 25.55). Teratomas are seen with a combination of fluid-filled cysts, fat, soft tissue and calcification.[96]

The Cardiophrenic Angle

The cardiophrenic angle is the space anterior and to the right of the heart, usually involves benign lesions such as fat, lipoma, pericardial cyst or Morgagni hernia.

The Retrotracheal Clear Space

The retrotracheal space includes structures posterior to the trachea, anterior to the thoracic spine and superior to the aortic arch. The normal structures in this area include the esophagus and lymph nodes. Abnormalities affecting the esophagus, such as tumor, achalasia, Zenker's diverticulum are seen in this region. Vascular structures, such as an aberrant right subclavian or thyroid masses, such as goiters, may also be seen in this area.[97]

The Subcarinal Region

This region is situated below the carina and above the left atrium. Normal structures include fat, lymph nodes and the esophagus. The differential diagnosis of lesions in this location consists of lymphadenopathy, bronchogenic cysts, esophageal diverticulum or tumors (Fig. 25.56).

The Retrocardiac Clear Space

This retrocardiac space exists behind the heart and in front of the thoracic spine. The structures located in this

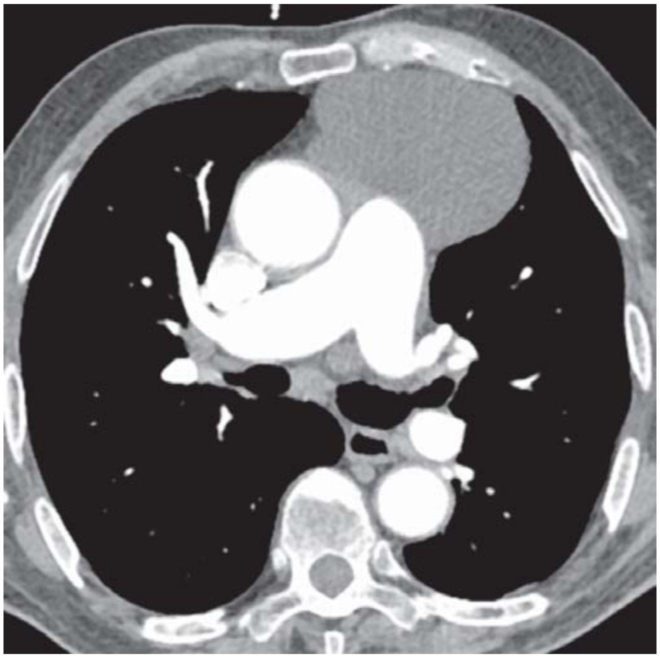

Fig. 25.55: CT chest (mediastinal window) illustrating a large mediastinal mass in the retrosternal clear space. Note the homogenous appearance. This is representative of a thymic cyst

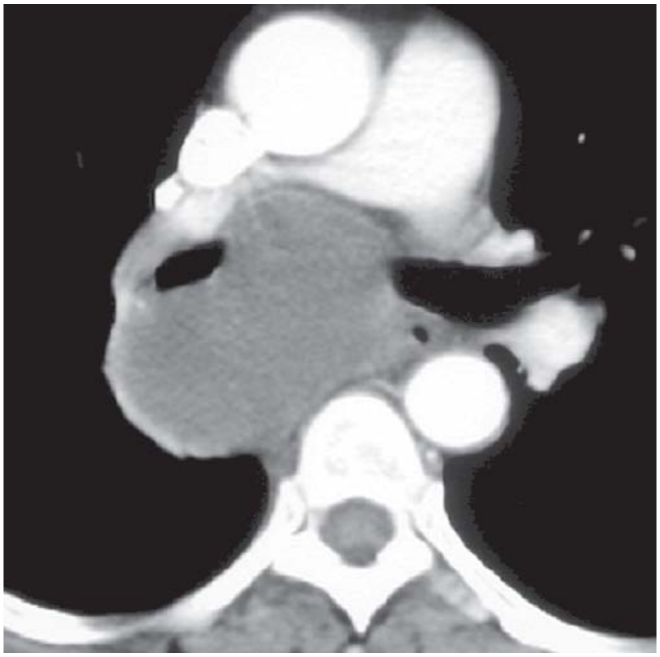

Fig. 25.56: CT chest (mediastinal window) demonstrating a large bronchogenic duplication cyst in the subcarinal region

space are the esophagus, aorta, azygous vein, fat and lymph nodes. Esophageal lesions, such as duplication cyst, varices, hiatal hernia and tumor, aortic aneurysm and lymphadenopathy may arise in this location.

The Posterior Mediastinum

The posterior mediastinum covers the region posterior to the anterior border of the vertebral bodies, where the vertebral column, fat and nerves are situated. The most common lesions in the posterior column are neurogenic and best imaged with MRI.

MISCELLANEOUS

Allergic Bronchopulmonary Mycosis

CT findings of ABPM include central airway abnormalities where there is bronchial dilatation with mucus-filled centrilobular bronchioles resulting in a tree-in-bud pattern[98] (Fig 25.57). Parenchymal abnormalities, such as consolidation, cavitation, bullae or scarring, as well as pleural abnormalities, including focal pleural thickening may also be evident.[99] Central bronchiectasis and mucoid impaction are specific findings in ABPM (Fig. 25.58).

Chronic Eosinophilic Pneumonia

The classic HRCT picture of chronic eosinophilic pneumonia is consolidation in a peripheral distribution confined primarily to the outer third of the lung and with an upper lobe distribution (Figs 25.59 and 25.60).

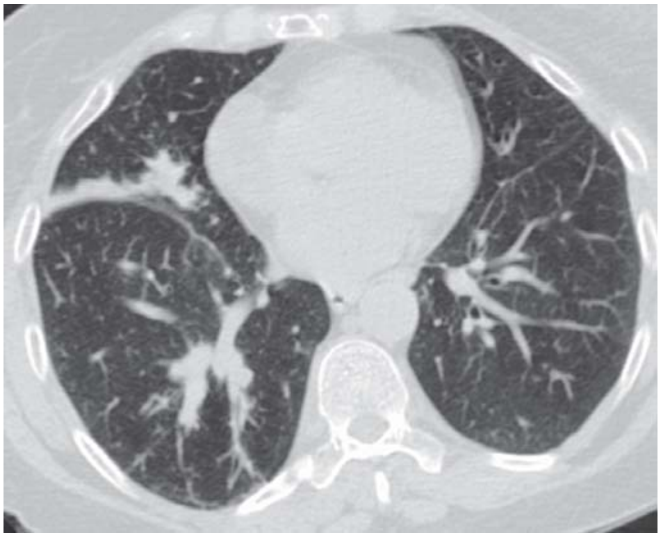

Fig. 25.57: CT chest showing insipation of bronchi in a patient with allergic bronchopulmonary aspergillosis

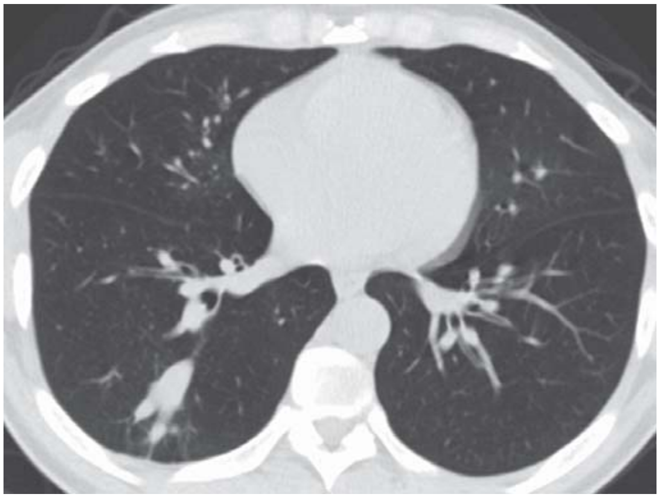

Fig. 25.58: CT chest in a patient with allergic bronchopulmonary aspergillosis showing insipation of the lower lobe bronchi

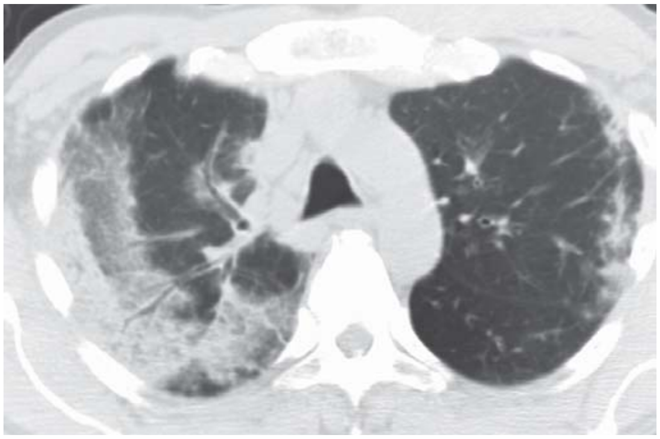

Fig. 25.59: CT chest with peripherally distributed opacities in a patient with chronic eosinophilic pneumonitis

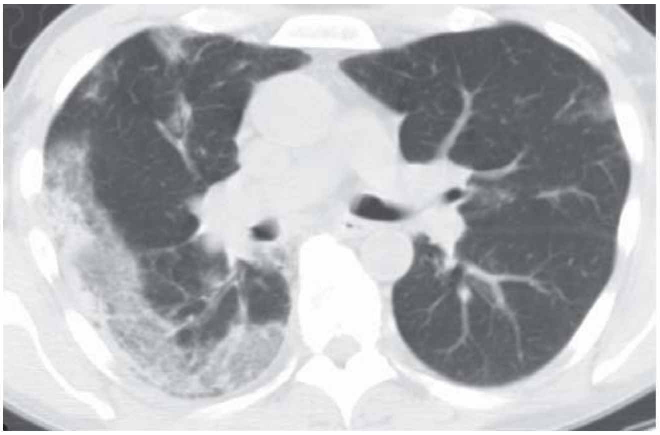

Fig. 25.60: CT chest in a patient with chronic eosinophillic pneumonitis with peripherally distributed opacities

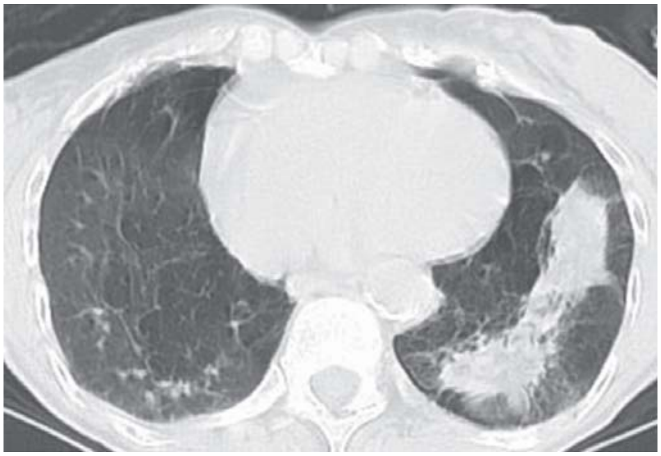

Fig. 25.61: CT chest representation of lipoid pneumonia

Lipoid Pneumonia

CT findings of lipoid pneumonia have been studied in a small number of cases. In the appropriate clinical context, CT may demonstrate solitary nodule resembling carcinoma, the localized area of consolidation or extensive bilateral opacities.[100] HRCT findings of lipoid pneumonia show parenchymal nodules or opacities containing fat (Fig. 25.61)

Drug-Induced Lung Disease

There are several manifestations of drug-induced lung disease. The most common include noncardiogenic pulmonary edema, hypersensitivity pneumonitis and chronic pneumonitis.[101] Noncardiogenic pulmonary edema had been described to occur after the administration of cytosine arabinoside, methotrexate and cyclophosphamide, resulting in a widespread airspace consolidation with predominance in the dependent lung regions. Hypersensitivity pneumonitis has been seen after methotrexate, cyclophosphamide and bleomycin administration. The HRCT findings of bilateral ground-glass attenuation in either patchy or diffuse distribution are seen. Chronic pneumonitis is the most common drug-induced lung disease reported with all cytotoxic drugs and causes reticular changes in the lower lungs as seen with IPF (Figs 25.62 and 25.63).

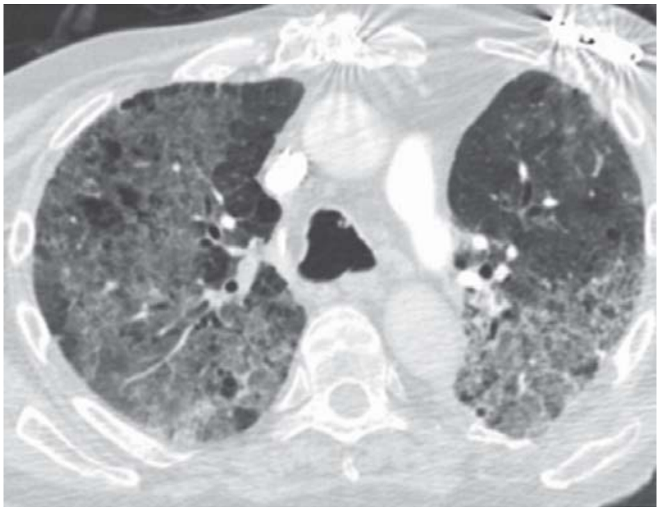

Fig. 25.62: CT chest showing diffuse fibrosis with ground glass attenuation in a patient with drug-induced lung disease

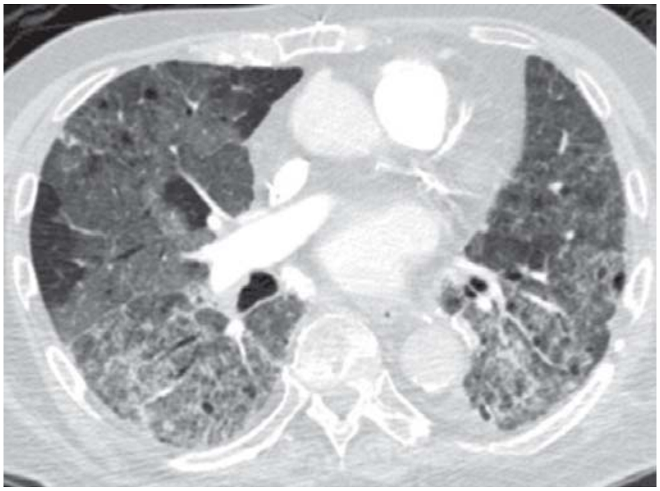

Fig. 25.63: CT chest showing diffuse fibrosis, increased density in drug-induced lung disease

CONCLUSION

The indications and role of CT imaging in the diagnoses of various thoracic diseases has been immensely influenced by a variety of technologic advancements. CT has become a fundamental part of the clinical decision making in a number of conditions involving the lung parenchyma, airways, vasculature and the mediastinum. Several characteristic features, such as ground-glass opacification, honeycomb changes, nodular features help narrow the differential diagnosis in many situations. These features depict the extent of disease processes and guide the course of management, eliminating the need for invasive diagnostic testing. It is therefore of paramount importance to understand and recognize the different CT features in thoracic conditions.

Pulmonary Function Testing

Ashutosh N Aggarwal

INTRODUCTION

Pulmonary function tests are designed to assess how well the lungs are able to perform their intended role. There is as yet no single test that can provide sufficiently detailed information on all the aspects of lung function. Instead, depending on the clinical scenario, one must do one or more procedures to answer a particular question. Further, the available options vary greatly in the terms of the ease of conducting the test, equipment and technician requirements, test performance characteristics, and procedure cost. As a result, not all investigations may be feasible, or even necessary, in a given setting. Of all pulmonary function tests available, spirometry is by far the most commonly used procedure, in the view of its relative simplicity, easy equipment availability, and the good standardization of test performance and interpretation algorithms. This chapter provides an overview of the physiologic principles, conduct, and interpretation of commonly used pulmonary function tests. The abbreviations and terminology used herein are outlined in Table 26A.1.

SPIROMETRY

Spirometry is the commonest and most widely used lung function test, although its true potential still needs to be realized. In many ways, its utility can be compared to blood pressure measurement or electrocardiography, in routine cardiac evaluation. However, one needs to pay careful attention to following standard procedures, while performing and interpreting the test. Because the residual volume in lungs cannot be exhaled, spiromteric measurements are limited to the vital capacity and its subdivisions (Fig. 26A.1).

Indications and Contraindications

There are multiple scenarios in which information obtained from spirometry may prove useful. The most common indication for doing the test is a functional evaluation of patients with lung disease. The presence of spirometric abnormalities, as well as the degree of impairment, provides useful information about the disease severity and pulmonary reserve of the patient. Often, the test is conducted to narrow the differential diagnosis of a patient being assessed for pulmonary disorder. For instance, the documentation of airflow limitation in a smoker being evaluated for breathlessness would increase the probability of the patient having Chronic Obstructive Pulmonary Disease (COPD). Because the test can be easily repeated, and the results are quite reproducible for a given patient, serial measurements can provide information about disease progression, as well as response to prescribed treatment.

The test also has an important role in clinical trials, as it is the best standardized objective surrogate for true pulmonary function. Spirometry is also used as a screening tool for studies in epidemiologic surveys, as it may provide an objective definition of disease state (such as bronchial asthma). It can also be used to screen at-risk populations for subclinical disease (for example pre-operative assessment or detecting COPD among asymptomatic smokers). The test is also utilized in occupational setting, both for detecting work-related respiratory disorders and for disability assessment in

TABLE 26A.1: Glossary of abbreviations and terms describing lung volumes and air flow

ERV	Expiratory reserve volume	Difference between the volume of air in lungs at end expiration during quiet breathing (functional residual capacity) and after forced exhalation (residual volume)
$FEF_{25\%-75\%}$	Forced midexpiratory flow	The average air flow in the middle half of a forced expiratory maneuver
FEV_1	Forced expiratory volume in first second	Volume of air exhaled during the first second of a forced vital capacity maneuver
$FEV_1\%$	FEV_1/VC	Ratio of forced expiratory volume in first second to the vital capacity (either forced or slow)
FEV_t	Forced expiratory volume in first 't' seconds	Volume of air exhaled during the first 't' seconds of a forced vital capacity maneuver (e.g. FEV_6 is the volume in first six seconds)
FRC	Functional residual capacity	Volume of air remaining in lungs at end expiration during quiet breathing
FVC	Forced vital capacity	Volume of air exhaled from a position of full inspiration to full expiration during a forced expiratory maneuver
IRV	Inspiratory reserve volume	Difference between the volume of air in lungs at end inspiration during quiet breathing and after maximal inspiration (TLC)
MVV	Maximal voluntary ventilation	Maximal volume of air that can be breathed in (or out) in one minute
PEF	Peak expiratory flow	The maximal air flow generated during a forced expiratory maneuver
RV	Residual volume	Volume of air remaining in lungs even after complete forced expiration
SVC	Slow vital capacity	Volume of air exhaled from a position of full inspiration to full expiration during a slow (or relaxed) expiratory maneuver
TLC	Total lung capacity	Volume of air within lungs at the end of full inspiration
VC	Vital capacity	Volume of air exhaled from a position of full inspiration to full expiration
V_E	Minute ventilation	Volume of air exhaled in one minute
V_t	Tidal volume	Volume of air breathed in (or out) in each respiratory cycle during quiet respiration

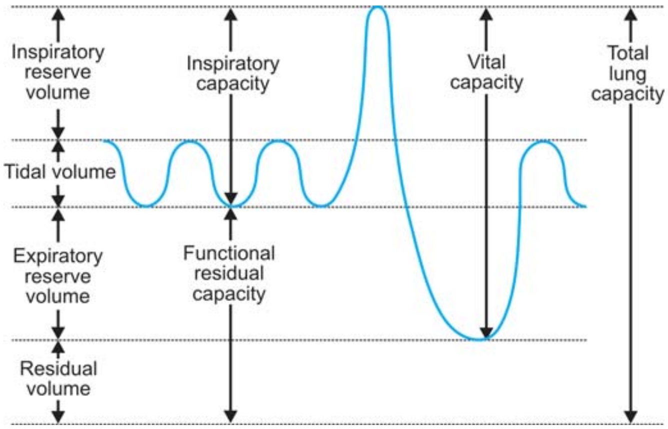

Fig. 26A.1: Various lung volumes and capacities in relation to the spirometry tracing. Note that residual volume cannot be determined through conventional spirometry

symptomatic people (for example as part of compensation procedures). Finally, spirometry is an important research tool for understanding pathophysiology and temporal course of several diseases, as well as for the derivation and validation of reference equations.

It is also important to understand when not to perform spirometry. Any benefit from the information obtained through this test should be carefully weighed against patient discomfort and risk. The test is better avoided in pregnant and severely dyspneic patients. It should also not be carried out in patients where pressure swings due to a forced expiratory maneuver can worsen existing conditions (such as ruptured tympanic membrane, bronchopleural fistula, ongoing hemoptysis, etc.). Uncooperative patients and those on life support systems, should also not undergo the test.

Equipment

A wide range of apparatus, ranging from handheld portable devices to large equipment, and from predominantly manual to completely automated systems, is available to perform spirometry. Although many factors, such as cost, patient load, clinical requirements, etc., determine the choice of machine, it is important to use one that confirms to some minimum technical specifications necessary to obtain valid results. Such recommendations for equipment performance were laid out by the American Thoracic Society, and have recently been updated as a joint recommendation from the American Thoracic Society and the European Respiratory Society.[1,2] The important performance criteria relate to accuracy (degree of conformity to the true value), precision (degree of repeatability of the same measurement) and resolution (minimum measurable incremental quantity). It is also advisable to have a system that can be calibrated periodically to ensure optimum performance.

Most commercially available spirometers nowadays are computerized systems that employ a transducer to convert a mechanical signal to an electrical one, and display the output in a fashion understood by the operator. These equipment can be divided into two broad categories: Volume displacement spirometers and flow-sensing spirometers. The former work with volume as the primary output, and flow is a derived parameter. Such machines can have a water seal, a dry-rolling seal or a bellows type design. Flow sensing devices can either be electronic turbines, or use electronic pneumotachometers (sensors that estimate airflow from the change in pressure occurring across a suitable resistance), which in turn can have a flow-resistive, a heated wire, or an ultrasonic design. As opposed to volume displacement spirometers, these machines measure flow as the primary signal, which is time-integrated to yield volume estimates.

Technique

The basic steps in patient preparation are outlined in Table 26A.2. Briefly, the patient is instructed to breathe gently through the mouthpiece from and into the spirometer. This accustoms him to breathing through the machine, and also generates a recording for tidal volume. Thereafter, a maximal inspiratory maneuver starting at tidal end expiration, followed by a forced expiratory maneuver, defines the forced vital capacity. It is extremely important that the technician supervising the test constantly encourages the patient throughout this procedure, to generate the best possible effort. Failing

TABLE 26A.2: A typical spirometry session

Pre-procedure preparation

- Ensure equipment integrity (electrical power, tubings, filters, etc.)
- Calibrate spirometer
- Verify indications/contraindications to the test
- Obtain informed consent for procedure
- Check personal and clinical details (age, gender, smoking habits, medications, diagnosis, previous tests, results of other investigations, etc.)
- Measure weight and standing height
- Explain (and preferably demonstrate) test procedure to the subject

Forced expiratory maneuvers

- Apply nose clip
- Place appropriately sized mouthpiece in the mouth, and ask subject to tightly close lips around it
- Ask subject to breathe gently from and into the mouthpiece for a few breaths
- At end-tidal expiration, ask subject to inhale as completely as possible
- Ask subject to exhale as rapidly, as completely, as forcefully, and for as long as possible, till no more air can be expelled out from the lungs; provide constant encouragement throughout
- Repeat for a minimum of three maneuvers

Optimize test quality

- Verify that each maneuver is technically acceptable
  - Satisfactory start of test (no hesitation)
  - Good duration (expiratory time preferably more than six seconds)
  - Free from artifacts (such as cough, submaximal effort, early glottic closure, premature termination of expiration, etc.)
- Check repeatability from among at least three acceptable maneuvers
  - Two largest FVC values within 150 mL of each other
  - Two largest FEV_1 values within 150 mL of each other
- Perform additional maneuvers if necessary, till repeatability criteria are satisfied

Check for bronchodilator reversibility (optional, but recommended)

- Ask patient to inhale 400 μg of salbutamol, preferably through a spacer attached to inhaler
- Wait for 15-30 minutes
- Repeat forced expiratory maneuvers as above, and verify test quality

Interpretation and reporting

- Compare observed values to predicted norms
- Look at shape, size and pattern of flow-volume loop
- Review available clinical information
- Categorize spirometry data into normal, obstructive or restrictive patterns
- Assess the severity of pulmonary function impairment (if any)
- Generate report, with comments on test quality and interpretation

this, not only will the test remain of poor quality, but the end-result may also be a falsely abnormal spirometry report. Several centers routinely perform postbronchodilator assessment as well. Although time-consuming, the additional information from this procedure is quite helpful, especially in the characterization of airflow limitation.

Quality assessment involves confirming the acceptability and reproducibility of multiple tests in same session. Detailed guidelines are available in this regard, and are summarized in Table 26A.2.[2] Acceptability should be tested for each individual maneuver in any spirometry session, whereas reproducibility assesses how well the results of individual "acceptable" maneuvers in any spirometry session match with each other. Each spirometry session should have at least three acceptable maneuvers from which reproducibility can be assessed. If three maneuvers do not meet reproducibility criteria then testing can be continued till these criteria are met. Normally, no more than eight maneuvers are recommended, as patients get fatigued beyond that.[3] If reproducibility criteria are not met even after eight attempts, testing should be concluded and interpretation performed from three best tests, making a note of this fact in the final report.

The start of expiration is usually defined by the back-extrapolation of the steepest portion of the volume-time curve to zero volume. The end of expiration is reached when the expired volume is less than 25 mL in one second or the subject cannot continue exhaling further. Normally, expiratory time should exceed six seconds. All measurements should be reported at Body Temperature and Pressure, Saturated (BTPS) conditions. This standardizes the readings to barometric pressure at sea level, body temperature, saturated with water vapor. Nomograms are available to derive correction factors based on the ambient atmospheric conditions.

Reference Values

The basic purpose of pulmonary function testing is to identify persons with abnormal lung function. To know what is abnormal, we must first define what is normal. Predicted normal values can be obtained from studies carried out in healthy subjects. They are usually in the form of a regression equation describing the predicted value as a function of gender and anthropometric data (e.g. height, weight, etc.), and differ greatly with ethnicity. For instance, the predicted value of FEV_1 among men is expressed as FEV_1 (L) = $-1.90 - 0.025A + 0.00006A^2 + 0.036H$ (*A age in years, H height in cm*) from the regression equation for north Indian adults being used at our laboratory.[4] Any value below the predicted normal is not necessarily reduced, since the normal value is a range rather than a fixed point. This introduces the concept of "lower limit of normal" or LLN, which can be defined in several ways. The simplest (and most widely used) method is to use a fixed percentage of predicted value. For example, a value less than 80% of predicted FEV_1 can be considered abnormal. However, there is very little statistical or physiological basis for such an approach.

A more valid approach is to use lower 95% confidence limits of the regression equation, or subtract 1.645 times the standard error of estimate of the regression equation from the predicted value, to define the LLN.[5] Any value below the corresponding LLN is considered abnormal. It is very important to use norms derived from individuals largely similar to the patients being generally tested at any pulmonary function laboratory. Therefore standard Caucasian norms, often incorporated into spirometer software, should be avoided, and locally appropriate reference equations applied wherever available. Reference equations for use in different geographic areas of India are available and should be preferably used.[4,6-13] Due to significant ethnic variability, these equations should not be interchanged with each other.[14] The common practice of using 85% or 90% predicted Caucasian values as the corresponding predicted value for north Indians is also statistically not valid.[15]

Interpretation and Patterns in Common Disorders

Interpreting lung function data is not just about looking at numbers generated by the spirometer. Both the volume-time curve and the flow-volume loop should also be evaluated with regard to their technical quality, size and shape, and various components, before making a final interpretation. Often such graphical analysis provides additional important information not obtainable from the numerical data. If available, the postbronchodilator graphs should also be similarly evaluated and compared to baseline curves. The clinical data provided in the requisition form is equally important in helping to reach any conclusion, especially in the borderline situations.

The most important action is to turn off computer-based interpretation, even if such software is offered with the machine. The initial step in interpretation is confirming that the test is of reasonably good quality (see above). Broadly, the interpretation of spirometric data involves only three numerical variables: FEV_1, VC and FEV_1/VC.[16] The largest observed values of FEV_1 and VC available from among at least three acceptable and reproducible tests should be used as the key parameters for interpretation, even if these individual observations are derived from different test maneuvers. If both forced and relaxed VC maneuvers have been performed, the larger value of VC amongst the FVC and SVC measurements should be used for the interpretation. The large number of other variables, often available from computerized spirometer outputs, usually provide no additional information, and are best excluded from a standard interpretative algorithm. It is well recognized that increasing the number of tests for interpretation is likely to increase the probability of falsely abnormal results.[17] These readings may however be used to arrive at a conclusion in borderline or difficult situations. Values clearly above or clearly below their respective LLNs can be interpreted confidently. Borderline values need interpretation with caution, often supplementing clinical information and/or other test results to make decisions.

Any spirometry record with normal FEV_1, VC and FEV_1/VC (i.e. all values more than their corresponding LLN values) should be interpreted as normal. Any spirometry record with FEV_1/VC value below its predicted LLN should be interpreted as having an obstructive abnormality (Fig. 26A.2). In situations where statistically valid LLN figures are not available (or not practical to use, as in field settings), FEV_1/VC ratio less than 70% is often used to define airway obstruction. However, this practice is likely to yield false positive results, especially in the elderly.[18] An obstructive defect is commonly seen in disorders associated with airflow limitation such as asthma and COPD. It may also be observed in diseases with small airway obstruction (such as bronchiolitis), cystic fibrosis, bronchiectasis, airway tumors, etc. Patients with upper airway obstruction can be further characterized based on appearance of flow volume loops.

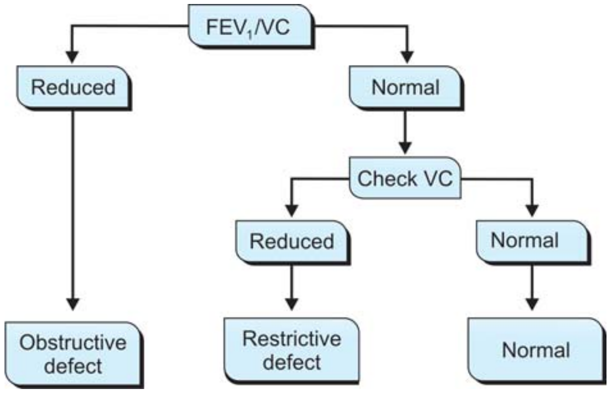

Fig. 26A.2: A basic algorithm for spirometry interpretation

Any spirometry record with a normal FEV_1/VC (i.e. value above corresponding LLN), coupled with a reduced VC (i.e. value below corresponding LLN), is suggestive of a restrictive abnormality. In situations where statistically valid LLN figures are not available (or not practical to use, as in field settings), observed VC ratio less than 80% of predicted value is often used to define reduction in VC. However, such an approach may result in the substantial misclassification of results.[19] Restrictive defects are common in conditions with the loss of functioning lung parenchyma (e.g. diffuse parenchymal lung diseases, lung collapse/atelectasis, pneumonia, after lung resection). Such defects are also observed in neuromuscular diseases (due to reduction in generation of force needed for a FVC maneuver), as well as disorders of chest wall and pleura (e.g. massive pleural effusion, pleural fibrosis, obesity, kyphoscoliosis).

It is important to note that spirometry can only suggest, but not confirm, a restrictive defect. True restriction is defined as reduction in total lung capacity. A mixed (obstructive plus restrictive) defect also cannot be diagnosed solely based on spirometry. A disproportionately low VC in the face of a reduced FEV_1/VC can either represent air trapping (with consequent increase in RV at the expense of VC, as in severe emphysema), or a true reduction in TLC (as in COPD with pneumonia). In such situations, it is advisable to estimate TLC (see below) for better characterization. FEV_1, expressed as a percentage of predicted normal value, is used to describe the severity of both obstructive and restrictive abnormalities. There is no universally accepted scheme of severity categorization.

More recently, some laboratories are shifting to FEV_6 as a substitute for FVC. Forced exhalation up to six seconds is a lot easier to perform for many patients. There are much less technical issues with the accurate measurement of low flow during prolonged expiratory maneuver, and the end of test can be more easily defined. FEV_6 may be more reproducible in several patients, especially those with airflow limitation. Reference equations for FEV_6 have also become available.[20,21] There is data to suggest that FEV_6 may be an acceptable surrogate for FVC in diagnosing both obstructive and restrictive defects on spirometry.[22,23]

The flow-volume loop may also provide a clue to underlying pathology (Fig. 26A.3). A small and concave or scooped curve suggests obstructive disorder. A small curve with steep slope suggests restriction. A small and flat curve suggests central airway obstruction. In disorders with variable intrathoracic obstruction, only the expiratory component of the loop is flat, whereas in

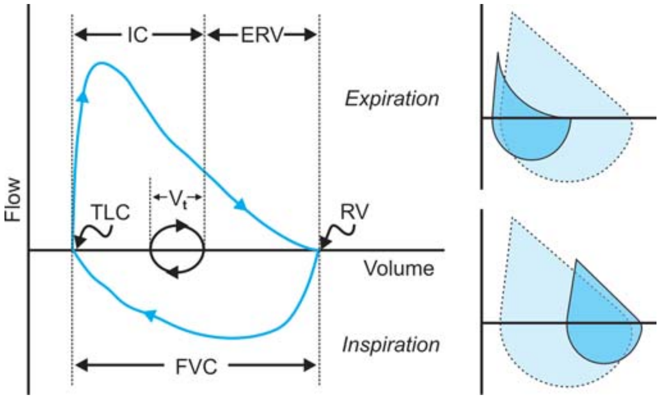

Fig. 26A.3: The left panel shows a typical flow-volume loop and the various subdivisions of lung volume. The right panel shows changes in the shape of flow volume loop in obstructive (top) and restrictive (bottom) defects, with the dotted line representing the normal loop

disorders with variable extrathoracic obstruction, only the inspiratory component is flat. Both components are flat in lesions causing fixed airway obstruction.

Bronchodilator Responsiveness (BDR) is considered to be present, if the increase in FEV_1 and/or VC (15–30 minutes after the inhalation of 400 µg salbutamol) in the post-bronchodilator study is both greater than 12% and greater than 200 mL over baseline values. Although an oversimplification, patients with asthma tend to have BDR much more frequently than those with COPD. It must be noted that the lack of BDR does not necessarily imply poor clinical response to bronchodilators in either condition.

PEAK EXPIRATORY FLOW

Peak Expiratory Flow (PEF) is defined as highest flow achieved from a maximum forced expiratory maneuver started without hesitation from a position of maximal lung inflation.[24] It can be measured either as a part of the spirometry procedure on the same instrument (with values derived from the flow volume curve), or separately using peak flow meters. The first meter specifically designed to measure this index of lung function was developed more than 50 years ago (Wright meter). Subsequently, a more portable, lower cost version (the ‘Mini-Wright’ peak flow meter) was developed, and other designs and copies have since then become available across the world.

Although PEF is fairly well reproducible for an individual, the normal range of PEF in healthy individuals is rather wide. As a result, predicted values of PEF cannot be used to detect lung disease, since there is substantial overlap between values in patients with lung diseases and normal persons. Further, since PEF recordings are both flow and volume dependant, they tend to get reduced in both obstructive and restrictive disorders. Hence the general notion that diminished PEF is a marker of airway obstruction is also not correct. While a normal PEF can reliably rule out airway obstruction, a low PEF does not necessarily indicate the same. The degree of reduction in PEF does not correlate well with the severity of obstruction described by the degree of reduction in FEV_1. PEF measurements generally underestimate the degree of airway obstruction, as determined from FEV_1 measurements.[25] This is partly because PEF predominantly reflects large airway function, while FEV_1 reflects both large and peripheral airway function. On the other hand, PEF is an extremely good tool for personal monitoring, especially among patients with bronchial asthma. Once a patient has established his/her personal best value, daily PEF monitoring can provide early clue to worsening airflow limitation due to impending exacerbation or poor control.

To measure PEF using a Mini-Wright meter, the indicator is moved to the bottom of the numbered scale. The subject then inhales deeply, and places the mouthpiece in his/her mouth, tightly closing the lips around it. The mouthpiece should be gripped between the teeth and over the tongue. A noseclip is not necessary. He/she then blows out as hard and fast as possible in a single blow. The procedure is repeated two more times and the highest reading from three successive blows is recorded. The largest two readings should be within 40 L/min of each other. It has been known for some time that the linear scale on the standard Mini-Wright PEF meter is an oversimplification, since the scale actually has nonlinear characteristics. As a result, the standard scale can over-record PEF in the mid-range by as much as 30%. However, this scale has continued to be used for diagnosing and managing asthma worldwide for nearly half a century. More recently, the requirements for equipment accuracy have been refined in a European Commission standard adopted in 2004.[26] The corresponding new Mini-Wright meters have an alinear scale that better reflects the true PEF (Fig. 26A.4). As predicted values for PEF have been obtained with meters with the old scale, these need to be converted to the new scale for data interpretation using the new meters. Nomograms and online converters are available for this purpose.

STATIC LUNG VOLUMES

Since spirometry cannot measure RV, it is not possible to determine FRC and TLC from this test. Other techniques are needed for the purpose. These methods

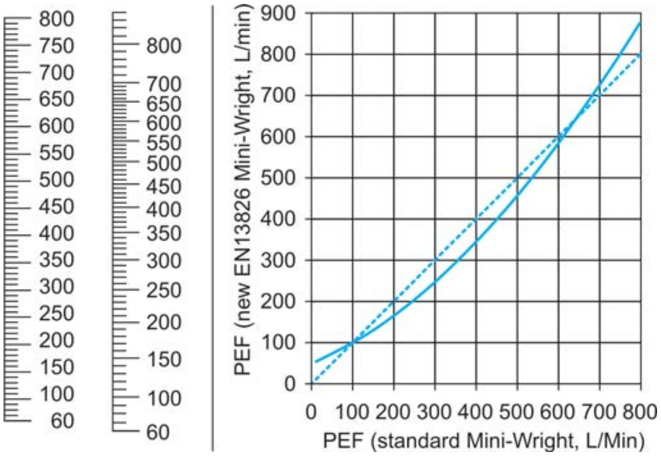

Fig. 26A.4: The left panel compares the standard and the newer (based on the EN13826 standard) scales used in Mini-Wright peak flow meters. Note that the standard meter (left) has a linear scale whereas the newer scale (right) is alinear. The right panel shows the direction and magnitude of error with the use of the standard scale, in comparison to the newer scale

$V_1 + FRC = V_2$
$FRC = V_1 \times \frac{He_1 - He_2}{He_2}$

Fig. 26A.5: Helium dilution technique to estimate functional residual capacity (FRC). Gas laws can be used to calculate FRC from initial and final helium concentrations (He_1 and He_2 respectively), and the known volume of helium mixture reservoir (V_1). See text for procedure details

are generally based on principles in which airflow velocity plays no role (in contrast to spirometry), and hence the term "static lung volumes" is often used for these measurements. Three techniques may be used: (a) open circuit nitrogen washout, (b) closed circuit inert gas dilution, and (c) whole body plethysmography. Determination of static lung volumes is helpful in ascertaining true restrictive physiology, and differentiating between obstructive and restrictive disorders. Comparison between TLC estimated through gas dilution and plethysmographic methods can also quantify the extent of air trapping within the lungs.

Open Circuit Nitrogen Washout Technique

In this method, the subject breathes 100% oxygen, starting from end-tidal expiration. This results in the washing out of nitrogen from the lungs. The exhaled gas is collected over the next 5–7 minutes, and its volume determined. Nitrogen concentration is measured through an analyzer in the breathing circuit and test stopped once a low plateau (concentration 1 to 2% for at least three successive breaths) is reached. The initial nitrogen concentration in the lungs is assumed to be similar to that in air. FRC can then be easily computed from the initial and final nitrogen concentrations, and the final collected volume. The technique has the drawback that any lack of precision in measuring nitrogen concentrations or expired volume will result in significant errors.

Closed Circuit Inert Gas Dilution Technique

The method is based on the equilibration of air in the lungs with a known volume of gas mixture containing a specified proportion of an inert gas (usually helium). The subject begins by tidal breathing through the mouthpiece. At end expiration of one such breath, he is connected to a reservoir containing a gas mixture with known helium concentration. Thus the point of starting the maneuver corresponds to the FRC. The subject continues to breathe in and out from this reservoir for about ten minutes, till the equilibration of gas between the reservoir and the lungs. The final concentration of helium is measured, and a simple calculation is used to derive the FRC (Fig. 26A.5). A vital capacity maneuver is performed at the same session to define the other lung volumes, which helps in computing the TLC and RV by addition or subtraction of the spirometrically determined IC and ERV respectively from the FRC. In view of the simple principles and technique, this method is widely used to determine static lung volumes.

Whole Body Plethysmography

In contrast to gas dilution techniques, plethysmography measures the total volume of air in the thoracic cavity, including gas trapped in bullae and other noncommunicating spaces (e.g. air within pleura or esophagus). Plethysmographically determined FRC is therefore often referred to as thoracic gas volume (TGV). Although several different types of body plethysmographs are available, the "volume constant" type is the most widely used. The equipment consists of a large air-tight chamber of known (and constant) volume. The subject sits inside this cabin and breathes through a mouthpiece till a stable end-expiratory level is obtained. At end-tidal expiration, a solenoid-operated shutter is used to occlude airway at the mouthpiece for 2–3 seconds, and the subject is asked to gently pant against the closed shutter with glottis open. As he breathes, chest expansion and retraction cause small pressure changes within the plethysmograph and at mouthpiece, which are recorded using pressure transducers (Fig. 26A.6). Since the plethysmograph volume is constant, these changes can be used to derive changes in the volume of air within the plethysmograph, and indirectly within the lungs. Pressure changes at the mouthpiece can be considered to directly reflect alveolar pressure changes, as the glottis is open and there is no net gas flow (due to the closed shutter). TGV can be computed from the slope of these pressure-volume curves using Boyle's law. Although the technique is cumbersome, it provides more reproducible measurements than dilution methods.

Interpretation

Reference equations for static lung volumes are used in a fashion similar to spirometry to define population limits of normality. In contrast to spirometry, an increase in TLC beyond the upper limit of normal is also considered pathological. A few regression equations are available in this regard from India as well.[6-11]

A decrease in TLC is diagnostic of a restrictive defect. In parenchymal restriction (e.g. lung fibrosis), RV and TLC are reduced proportionately, resulting in a normal RV/TLC ratio. In extrapulmonary restriction (e.g. chest wall or neuromuscular disorders), RV is usually normal (or sometimes even increased), resulting in an increased RV/TLC ratio. On the other hand, TLC might be increased in acromegaly, or in conditions like emphysema, as a result of air trapping. An increase in RV/TLC ratio, with an obstructive defect on spirometry, is a good indicator of air trapping. In conditions characterized by noncommunicating air in the lungs (e.g. emphysema, bullae, etc.), whole body plethysmography provides a better estimate of the lung volume, since gas dilution techniques measure only the volume of air that is freely exchanged during breathing. In fact, the difference in volumes calculated by the two techniques may provide some indication to the volume of noncommunicating air present in the lungs.[27] Estimation of static lung volumes is also necessary to diagnose mixed obstructive-restrictive defects, with a combination of reduced FEV_1/VC ratio and reduced TLC.

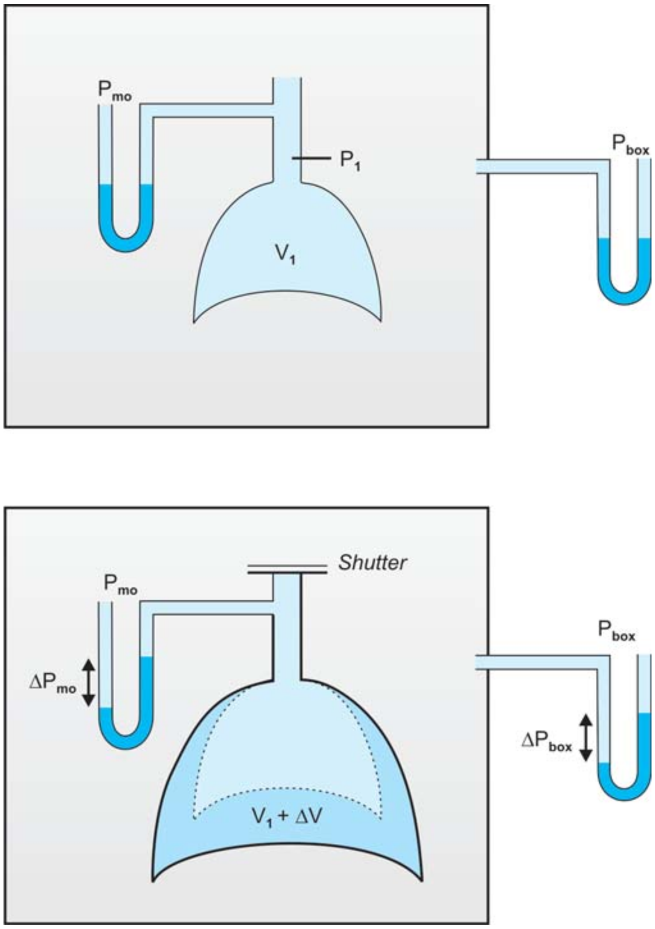

Fig. 26A.6: Whole body plethsmography to calculate static lung volumes using a constant volume apparatus. Under static conditions, pressure at mouth (P_{mo}) corresponds to the alveolar pressure (P_1), which is atmospheric at baseline. As the subject pants against a closed shutter, small fluctuations in mouth pressure (ΔP_{mo}) reflect alveolar pressure changes, while small fluctuations in lung volume (ΔV) are recorded as corresponding changes in pressure inside the plethysmograph chamber (ΔPb_{box}). A standard constant, specific to the plethysmograph being used, can be applied to compute ΔV from ΔPb_{box}. If the shutter is closed at tidal end-expiration, then gas laws can be used to compute functional residual capacity (V_1) from these data. See text for procedure details

DIFFUSING CAPACITY OF LUNGS

Measurement of pulmonary diffusing capacity allows us to assess the ability of lungs to transport gas from inspired air to the red blood cells in pulmonary capillary network. It is however, a misnomer, since gas transfer does not depend solely on diffusion across the alveolo-capillary membrane, and it is not a "capacity" in that there is no theoretical maximal limit. Many laboratories therefore employ the term "transfer factor" instead.

The Diffusing Capacity for Carbon Monoxide (DLCO) is the generally measured index. This is because carbon monoxide uptake is easily measurable, and the gas essentially follows the same pathway as oxygen during transport from alveolar air to red blood cells, and ultimate binding to hemoglobin. DLCO is the uptake of carbon monoxide from lungs per unit time per unit of carbon monoxide driving pressure. The test is usually performed for the screening of diffuse lung diseases and pulmonary vascular disorders; precise characterization of airflow limitation; differential diagnosis and severity assessment of restrictive ventilatory defects; disability evaluation; and preoperative assessment. There are no absolute contraindications. However, for technical reasons, most machines cannot measure DLCO in individuals with an extremely low VC (usually <1.5 liters) or severely dyspneic patients unable to hold breath for a sufficient time. The test cannot be performed on many patients receiving supplemental oxygen, as this needs to be discontinued before and throughout the test procedure.

Methodology

DLCO can be measured using a single-breath method, an intrabreath method or a rebreathing technique. The first is most commonly used, as it is simpler and better standardized (Fig. 26A.7). The gas mixture used contains 0.3% carbon monoxide, a tracer gas (helium, methane or neon), 21% oxygen, and balance nitrogen. The subject first gently breathes room air through a mouthpiece. Once comfortable, he is instructed to exhale completely (though not forcefully). At RV, he is connected to a reservoir containing the gas mixture, and instructed to inhale fully up to TLC, in less than two seconds. At this point he is asked to hold his breath for approximately ten seconds, without straining. Thereafter, he exhales fully, smoothly and quickly, and the expired gas is collected. The initial 0.75 to 1.0 liter is discarded as it represents dead space, and the next 0.5 to 1.0 liter is collected for analysis. Some instruments use rapid analyzers that provide real-time gas concentration curves from the exhaled gas, and allow washout till the tracer gas concentration reaches a plateau and collection subsequently. The collected mixture is analyzed for final tracer gas concentration and carbon monoxide uptake. For the purposes of analysis, the breath hold time is more than the actual breath holding period. The Jones-Meade method measures breath-hold time starting at 30% of inspiratory time and extending to half of the sampling time.[28]

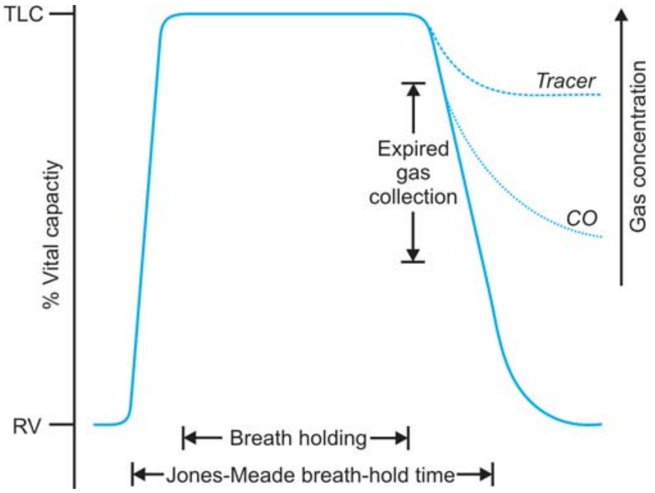

Fig. 26A.7: Schematic representation of the estimation of pulmonary diffusing capacity using the single breath technique. The subject inhales the gas mixture deeply residual volume (RV) to total lung capacity (TLC), and holds breath for ten seconds. Expired gas is collected after discarding that from dead space. Note that breath holding time used for calculations (see reference 28) is slightly longer than actual breath-hold. See text for procedure details

DLCO is calculated from the total lung volume, breath-hold time, and the initial and final alveolar carbon monoxide concentrations. It is a product of the subject's total lung capacity and rate of carbon monoxide uptake during the breath-hold time. An estimate of the total lung capacity and the initial alveolar carbon monoxide concentration is obtained from the tracer gas concentration in exhaled gas.

The test can be repeated after an interval of at least five minutes. Generally, a mean value is reported from two acceptable tests whose results agree within 2 mL/min/mm Hg.

Interpretation

In contrast to other pulmonary function tests, observed DLCO values must be normalized to key nonrespiratory variables. Hemoglobin concentration is important as it removes the carbon monoxide from the blood, thus providing a nearly constant gradient for gas transfer. Anemic patients may thus have a lower DLCO, and the measurement should therefore be corrected for this factor in such patients.[29,30] Smokers tend to have a small baseline level of blood carbon monoxide, and thus the transfer gradient may be less than for nonsmokers. If available, blood carboxyhemoglobin levels may be used to compensate for this anomaly.[30,31]

As with other lung function tests, the patient's result is interpreted by comparing it with a corresponding reference value. Regression equations for use in Indian subjects are available.[10,11,32] It must be noted that the degree of variability of DLCO (both for a given subject and for the population) is much higher than the results of other lung function tests. In case serial tests are performed, a DLCO result can also be compared to previous values to detect any sizeable change. Normalizing the DLCO to patient's alveolar volume may provide additional information about the reason for an abnormal result. When alveolar volume is reduced (either because of true restriction or due to noncommunicating air spaces), the ratio of DLCO to alveolar volume is relatively preserved. The ratio is however decreased if alveolar volume is increased (as in emphysema) or normal (as in anemia or nonperfusion of ventilated alveoli).

EXERCISE TESTING

Exercise testing is generally indicated for (a) evaluation of exercise intolerance, (b) evaluation of unexplained breathlessness, (c) preoperative assessment, and (d) formulation of exercise prescriptions. Detailed evaluation can give some clue about whether the underlying disorder is predominantly cardiovascular or respiratory in origin. Exercise testing can range from gross and crude assessments to highly detailed and standardized evaluation using computerized equipment. The two most regularly employed types of exercise testing for evaluating pulmonary diseases are the Six-Minute Walk Test (6MWT) and a formal complete Cardiopulmonary Exercise Testing (CPET).

Basic Modalities

Stair climbing remains the most basic exercise test that asks patients to climb stairs till they get limited by symptoms.[33] There is, however, no consensus on how to standardize the procedure, and several variations (such as climbing at own pace or at brisk pace, climbing with or without holding handrails) are used. Results are generally reported as number of stairs or number of flights of stairs.

Step tests ask the subject to walk up and down on a stool or bench at a specified rate. Several variations exist with regard to the height of steps, number of steps, and the frequency of step-ups. The most popular is the Master's two-step test.[34] The test is well suited to field use, and subjects can achieve close to their maximal exercise capacity.

The 6MWT is a simple procedure that assesses the maximum distance that a subject can walk on flat surface at his/her own pace in six minutes. The test provides a global estimate functional capacity, but does not give any specific information on individual systems (cardiac, pulmonary, hematologic and musculoskeletal) involved in exercise. The test is also sensitive to patient effort. The 6MWT is the most popular among the basic exercise tests as it is simple, practical and well standardized, and involves an activity familiar to almost everyone. A measured corridor, usually about 30 meters, is used, and the subject walks to and fro in this space at a self-determined pace. If a long corridor is not available, the test can be performed on a treadmill, although pacing and control are not as optimal and the distance walked is usually less.[35] Guidelines are available regarding the standardization, performance, and interpretation of the 6MWT.[36] The test has good reproducibility and good correlation with other measures of functional status.[37] For this reason, the 6MWT is the preferred investigation when a complete CPET is not available.

The shuttle walk test uses an audio signal from a metronome to dictate the walking pace.[38] Walking speed is incrementally increased every minute while the subject walks to and fro on a ten meter straight path. The test is terminated when the subject can no longer maintain the required speed. Hence the test correlates better with maximal symptom limited tests, such as the CPET, rather than the submaximal tests like 6MWT.[39] However, the test is more complicated than 6MWT, and may result in more frequent cardiac complications in the absence of electrocardiographic monitoring.

Exercise testing may sometimes be used to diagnose airway hyperreactivity due to exercise in patients with unexplained dyspnea. Exercise-Induced Bronchospasm (EIB) is described as a self-limiting bronchospastic event occurring immediately after strong exercise. Typically, greater than 10 to 15% reduction in FEV_1 and/or FVC is observed.[40] EIB is caused by the loss of heat, water or both, from the airways during exercise.

Cardiopulmonary Exercise Testing

The CPET is a more complex investigation that involves exercise at incrementally increasing intensity. The test is terminated when symptoms limit further exercise, or the maximal exercise capacity is achieved. A computerized protocol provides breath-by-breath information on respiratory gas exchange, airflow, oxygen consumption, carbon dioxide production, and cardiac variables (such as heart rate, blood pressure, etc.). The subject exercises on either a treadmill or on a bicycle ergometer; the latter may however be preferable as work rate can be directly measured.

Electrocardiographic and noninvasive blood pressure monitoring accompanies the test. In addition, oxygen saturation is continuously monitored through pulse oximetry. Real-time data on ventilatory and gas exchange parameters is obtained by asking the subject to breathe through a mouthpiece connected to a spirometer and metabolic cart. Flow, volume, and exhaled oxygen and carbon dioxide concentrations are measured. Either incremental or constant work protocol can be used. The test is terminated when the subject (a) gets exhausted, fatigued or distressed; (b) develops signs of cardiovascular instability (ischemia, arrhythmia, substantial blood pressure elevation, etc.); or (c) develops significant hypoxemia.

Although data for a large number of monitored and calculated variables is generated, interpretation and clinical correlation depends on the judicious integration of all available information. No single parameter is diagnostic of a cause for exercise limitation. Four basic measurements are critical in describing the response to exercise: oxygen consumption, carbon dioxide production, heart rate and minute ventilation. Under steady state conditions, measured oxygen uptake (Vo_2) equals metabolic oxygen consumption, and measured carbon dioxide output (Vco_2) is the same as its metabolic production. Both Vo_2 and Vco_2 can be mathematically computed from expired gas concentrations. Vo_2 increases linearly with work intensity until limitations in cardiac output and/or tissue extraction result in a plateau. This level is termed Vo_{2max} and is the best index for aerobic capacity. At lower work levels, Vco_2 increases at a rate similar to Vo_2. However, at higher work levels, the bicarbonate buffering of increased lactic acid production (resulting from anaerobic metabolism) causes Vco_2 to rise more steeply. The point where the Vco_2 begins to rise disproportionate to the Vo_2 is termed "anaerobic threshold" (Fig. 26A.8), and is a marker for the onset of metabolic acidosis during exercise. It usually occurs at 50 to 60% of Vo_{2max} with a wide range of normal values. The ratio between Vo_2 and heart rate reflects the amount of oxygen consumed in each cardiac cycle, and is often termed "oxygen pulse."

CPET is used to find whether or not a subject's maximal exercise capacity is decreased. A reduction in Vo_{2max} is the starting point for evaluating impaired exercise capacity. The quantum of this reduction is a rough indicator to the severity of exercise limitation. If Vo_{2max} is reduced, the other variables are then integrated into decision making to arrive at the most probable cause. In this regard, CPET is not clearly diagnostic of any individual disease process, but can rather only suggest the likely physiologic mechanism of dyspnea or exercise limitation. The cardiovascular response is assessed through anaerobic threshold, oxygen pulse, and relationships of Vo_2 to heart rate and work intensity. The ventilatory response is assessed through respiratory reserve (peak V_E/MVV), maximal respiratory rate, and arterial Pco_2 (if available). Gas exchange is assessed through physiological dead space assessment, oximetry, arterial oxygenation (if available), and calculating alveolo-arterial oxygen gradient ($P_{A\text{-}a}O_2$). Based on these assessments, and taking into account the overall clinical information, the etiology of exercise limitation can be deduced. The three basic causes for exercise limitation are cardiovascular disorders, respiratory disorders and physical deconditioning (Table 26A.3). However, one must be careful as significant overlap exists between response patterns in different disease conditions.

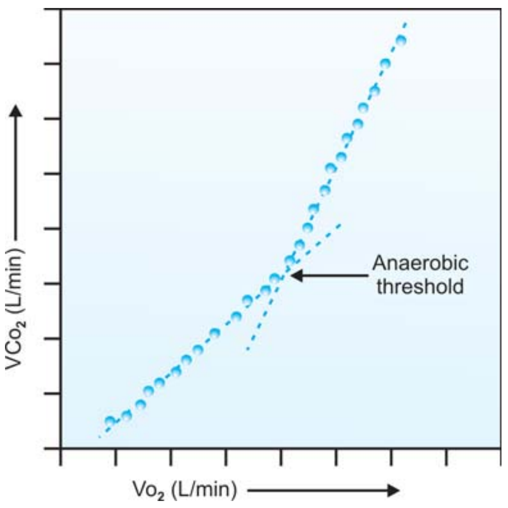

Fig. 26A.8: Anaerobic threshold determined from a plot of oxygen uptake (Vo_2) and carbon-dioxide production (Vco_2) during cardiopulmonary exercise testing

The test is highly sensitive in the identification of subclinical disease than other lung function tests conducted at rest. Therefore, CPET can be performed for preoperative assessment, disability evaluation, and the selection of candidates for heart and/or lung transplantation. The test is also useful in determining whether breathlessness results from cardiac or pulmonary component among patients who have disorders of both organ systems.

TABLE 26A.3: Typical responses during cardiopulmonary exercise testing

Parameter	*Normal value*	*COPD*	*ILD*	*Pulmonary vascular disease*	*Heart failure*	*Obesity*	*Decondition*
Vo_{2max}	>84% predicted	↓	↓	↓	↓	↓	↓
Anaerobic threshold	>40% of predicted Vo_{2max}	↔/↓	↔/↓	↓	↓	↔	↔/↓
Peak heart rate	>90% of age predicted	↓	↓	↔/↓	Variable	↔/↓	↔/↓
Oxygen pulse	>80%	↔/↓	↔/↓	↓	↓	↔	↓
Peak V_E/MVV x 100	<85%	↑	↔/↑	↔	↔/↓	↔/↑	↔
V_E/Vco_2 (at AT)	<34	↑	↑	↑	↑	↔	↔
Dead space/Tidal volume	<0.30	↑	↑	↑	↑	↔	↔
P_aO_2	>80 mm Hg	↔/↓	↓	↓	↔	↔	↔
$P_{A\text{-}a}O_2$	<35 mm Hg	↑	↑	↑	↔	↔/↓	↔

AT: Anaerobic threshold; COPD: Chronic obstructive pulmonary disease; ILD: Interstitial lung disease; MVV: Maximum voluntary ventilation; $P_{A\text{-}a}O_2$: Alveolo-arterial oxygen gradient; P_aO_2: Partial pressure of arterial oxygen; Vco_2: Carbon-dioxide production; V_E: Minute ventilation, Vo_{2max}: Maximal oxygen consumption

OTHER TESTS

Airway Hyperresponsiveness

Airway Hyperresponsiveness (AHR), a characteristic feature of bronchial asthma, is an increased sensitivity of airways to a variety of inhaled agents. AHR is classically measured using inhalation challenges with airway constrictor agonists, such as histamine or methacholine, which result in direct bronchoconstriction. Recently, inhaled mannitol solution has also become available for this purpose and acts by inducing osmotic changes in the airway.[41] Exercise can also be used to test for AHR (see above).

In general, histamine or methacholine solution is freshly prepared in doubling dilutions. After baseline spirometry, the subject inhales progressively increasing concentrations of the provocative agent through a dosimeter or nebulizer. Spirometry is repeated 30–90 seconds after each inhalation, and a rest of up to five minutes is provided between two successive inhalations. Several dosing protocols are in vogue, but the two most commonly used are (a) two-minute tidal breathing method and (b) five-breath dosimeter method.[40] The results are reported as percentage decrease in FEV_1 from the baseline, and summarized through an index termed PC_{20} (provocative concentration causing 20% reduction in FEV_1). PC_{20} is interpolated from a graph plotting FEV_1 values against the logarithm of provocator concentration. For methacholine, values higher than 20 mg/mL are normal, and values less than 4 mg/mL suggest AHR.[40] Resuscitation equipment should be available during testing, as sometimes life-threatening bronchospasm can result from the procedure.

Airway Resistance

Airway resistance can be clinically estimated using several approaches such as interrupter technique, forced oscillation technique and whole body plethysmography. The interrupter technique is the simplest, and requires monitoring airway pressure and airflow. Flow is abruptly interrupted, and airway resistance is obtained by dividing the pressure change after interruption by the flow obtained immediately before the interruption. Forced oscillation technique measures airway resistance by imposing flow oscillations on the airways during spontaneous breathing. These cyclical waves result in slight shifts in airflow, and consequent changes in airway pressure. Airway resistance is computed from pressure and flow changes, and frequency. The technique can provide added information about contributions from central and peripheral airways to the total airway resistance. When using the plethysmograph, the subject instructed to pant slowly, before and after the shutter at mouth is closed. Airway resistance is computed as the ratio between the slopes of mouth pressure-plethysmograph pressure and air flow-plethysmograph pressure changes.[42] This value can also be standardized to the lung volume by multiplying it by the simultaneously determined TGV. The resultant index is called specific airway resistance, and its reciprocal is termed as specific conductance.

Airway resistance is not normally determined for clinical purposes, but may provide additional information in the evaluation of patients suspected to have obstructive disorders. The range of normal airway resistance is not well defined, and generally values higher than 2.8 cm $H_2O/L/s$ are considered abnormal.

Pulmonary Mechanics

The elastic properties of the lungs are determined by relating alterations in the volume of air in the lungs to the corresponding changes in the lung's recoil. A body plethysmograph is usually used to determine the static pulmonary mechanics. Lung recoil force is measured as the transpulmonary pressure. This is the difference between the alveolar and pleural pressures; the former is measured at mouth under static conditions with shutter at mouth closed and glottis open, and the latter is quantified through pressure measurement from a thin balloon placed in the lower third of esophagus and connected to a pressure transducer. The subject sits in a whole body plethysmograph. After a few tidal breaths, he inspires fully to TLC, then exhales to FRC and again inspires to TLC. During the subsequent exhalation, a shutter at mouth occludes the airway intermittently. Mouth and esophageal pressures are recorded at each occlusion. Since mouth pressure equals alveolar pressure under static conditions, the transpulmonary pressure can be calculated at each shutter closure. This data is integrated with volume measurements to plot the relationship between transpulmonary pressure and lung volume. The slope of this curve over a range corresponding to the tidal volume is the static lung compliance. The whole plot can also be analyzed through a monoexponential analysis to yield a shape constant for the curve.[43] Unlike lung compliance, the shape constant is largely independent of ethnicity, patient effort and lung size. In patients with restrictive ventilatory defects, exponential analysis helps to differentiate restriction due to reduced elastic properties from that due to the loss of lung volume.[44]

Respiratory Muscle Function

Estimation of maximal respiratory pressures are a simple technique to assess global respiratory muscle function. A manometer is used to record highest pressures during maximal inhalation and exhalation, which can be sustained for at least one second.[45] Maximal Expiratory Pressure (MEP) is roughly twice as much as Maximal Inspiratory Pressures (MIP). The test is commonly used during the evaluation of respiratory muscle weakness in patients with neuromuscular disorders. It is also used as one of the several parameters to assess weaning potential in patients receiving mechanical ventilation. Abnormal muscle strength is identified by comparing observed values to reference data; such data is also available for the Indian population. Values are generally higher among men, and decline with age. A reduction in both MIP and MEP indicates generalized skeletal muscle weakness. A low MIP with normal MEP suggests isolated inspiratory muscle weakness (usually diaphragmatic). Isolated expiratory muscle weakness (normal MIP and low MEP) is rare.

The Sniff Nasal Inspiratory Pressure (SNIP) is a noninvasive test of inspiratory strength. The test is performed by wedging a catheter into one nostril and asking the subject to sniff through the other nostril. Pressure is measured in the obstructed nostril. The SNIP correlates strongly with transdiaphragmatic pressure and the MIP, but provides no information on expiratory muscle function.

Transdiaphragmatic pressure can be measured after the insertion of esophageal and gastric balloon catheters. This allows functional assessment during inspiration, expiration, a sniff, a cough or phrenic nerve stimulation. Although the technique is highly complex and invasive, it is the best measure of respiratory muscle strength. However, a wide normal range limits its clinical utility.[45]

Control of Breathing

The tests available to assess the respiratory control system include (a) inhalation of hypoxic or hyperoxic gas mixtures to stimulate chemoreceptors and (b) sleep studies to monitor behavior of the control system during sleep.[45] The hypoxic ventilatory response is evaluated by administering an hypoxic gas mixture to the subject over four to six minutes through a rebreathing circuit. This results in progressive hypoxemia, stimulation of peripheral chemoreceptors and an increase in respiratory drive. Blood CO_2 is maintained at the same level by removing CO_2 from the rebreathing bag. The ventilatory response is biphasic, with an initial rapid increase in ventilation followed by a gradual decline to a plateau. Ventilatory response to hypercapnia is determined by asking the subject to rebreathe a hyperoxic gas mixture, thereby causing progressive hypercapnia over four to six minutes. This results in the stimulation of central chemoreceptors, as well as an increase in the respiratory drive. End-tidal carbon dioxide tension is also monitored. The rise in ventilation in response to hypercapnia is linear. In either test, the measurements of ventilation or occlusion pressure are used to assess motor output. Occlusion pressure is assessed using $P_{0.1}$, which is the pressure generated in first 100 milliseconds of inspiration against an occluded airway.

Respiratory Muscle Function

Randeep Guleria

INTRODUCTION

Breathing, which is essential for life, requires the repetitive contractions of the muscles of respiration. Proper functioning of respiratory muscles is essential and unlike limb muscles, the muscles of breathing have no opportunity to rest and have to work throughout life. Besides breathing, respiratory muscles also play a role in other functions like sneezing, coughing, defecation, urination and parturiition. The respiratory muscles are an important component of the "respiratory pump" which consists of the respiratory center, and the conducting nerves, the thoracic cage and the muscles of breathing.[1] Till a few years ago, little attention was paid to respiratory muscles in the field of pulmonary medicine. A better understanding of respiratory muscle pathophysiology, the realization of the important role of respiratory muscles that they play in different diseases and the development of newer tests to more accurately assess respiratory muscles function have lead to an increased interest in this area.[2-4] Respiratory muscle training has also emerged as a treatment modality in patient with chronic respiratory diseases. A basic knowledge of the anatomy and physiology of the respiratory muscles is therefore important to properly understand their actions and the tests used to assess their functions.

Respiratory Muscles – Anatomical Considerations

The respiratory muscles can broadly be divided into two categories; those that take part in inspiration and those that are predominantly expiratory in function. In a normal person, during quite inspiration, the respiratory muscles contract in a coordinated manner so that the diaphragm moves down like a piston and the rib cage move upwards and outwards in a bucket handle manner. This increase in the size of the thoracic cage creates a more negative pleural pressure and air is drawn into the lungs. Besides this, during inspiration, as the airway pressure becomes negative, other muscles also act and prevent collapse of the conducting structures mainly in the upper airways. These muscles are the pharyngeal constrictor muscles, the genioglossus and the neck strap muscles.[5] These muscles ensure patency of the upper airways during inspiration. Also, the laryngeal abductor muscles contract and open the vocal cords during inspiration. All these muscles must act in synchrony to ensure adequate breathing during inspiration.

Expiration during normal breathing is usually passive. At the end of inspiration the inspiratory muscles relax and the normal elastic recoil of the lung facilitates expiration. During activities such as exercise and in patients with underlying lung disease, expiratory muscles may be recruited for a more active and forceful exhalation.

Inspiratory Muscles

Diaphragm: The diaphragm is the main muscle of inspiration and during quiet breathing, accounts for about 70 to 80% of the work of breathing.[6] The diaphragm is composed of two distinct muscle components, the costal portion and the crural portion.[7] Both of these are inserted into a central tendon. The costal portion arises anteriorly from the xiphoid process and from the upper margin of the lower 6 ribs. The thick crural portion consists of muscle fibers that arise from the arcuate ligaments and are inserted into the upper three lumbar bodies on the right side and the upper two lumbar vertebrae on the left side.[8] The costal and crural parts of the diaphragm may be recruited differently especially when an individual is breathing at a high ventilatory rate.

The diaphragmatic curvature is like that of a hemisphere. If the radius of this hemisphere were to be r, than as per Laplace's law the pressure inside the sphere (P) would be equal to 2 T/r, where T is the tension in the wall. If T is kept constant and r increases, as would happen if the diaphragm flattens and the curvature of the diaphragm decreases, it will lead to a decrease in pressure.[9] This commonly occurs in patients with Chronic Obstructive Pulmonary Disease (COPD) where flattening of the diaphragm due to emphysema or air trapping occurs and decreases the efficiency of the diaphragm to generate pressure. Also, the dome shape of the diaphragm increases diaphragmatic function through the zone of apposition. The zone of apposition is that part of the diaphragm that lies next to the inner aspect to the rib cage. When the diaphragm contracts and descends, it increases intra-abdominal pressure. This increased intraabdominal pressure is transmitted laterally to the rib cage and through the zone of apposition it facilitates the expansion of the lower rib cage.[8,9]

Besides the diaphragm, other muscles also contract during normal inspiration. These are mainly the scalene muscles, the intercostals and the triangularis.[54] The scalene muscle originates from the transverse process of the lower five cervical vertebrae. It is inserted on the upper surface of the first and second ribs. These muscles act by lifting and expanding the rib cage during inspiration.

This muscle was initially thought to be an accessory muscle of inspiration, but studies have clearly shown that the scalene are primary and not accessory muscles of inspiration.[10] The intercostals muscles consist of the external and internal intercostals, these muscles run between the ribs. The external intercostals and the parasternal part of the internal intercostals also contract during inspiration. Contraction of these muscles lifts the ribs and thereby increases the anteroposterior diameter of the rib cage.[11]

Accessory Inspiratory Muscles

As the ventilatory demand increases, the accessory muscles of inspiration come into play. The sternocleidomastoid is the most important accessory muscle of inspiration.[11] This muscle runs from the mastoid process and attaches to the medial third of the clavicle, the ribs and the manubrium sterni. Contraction of this muscle leads to the elevation of the first rib and lifting of the sternum. This results in an increase in the anteroposterior diameter of the upper part of the rib cage. The external intercostal muscles may also contract as ventilatory demand increases. Other muscles like the Pectoralis major and minor, latissmess dorsi, anterior serratus and trapezius, though not muscles of respiration, actively contract in patients with severe obstructive lung disease.[5]

Expiratory Muscles

Expiration in a normal individual is a passive process, achieved by the elastic recoil of the lung when the muscles of inspiration relax. The abdominal muscles assist expiration. These include rectus abdominis, external and internal oblique and transverse abdominis.[6] Contraction of these muscle decreases the size of the rib cage and the end expiratory lung volume also decreases. Also, as these abdominal muscles contract, the intra-abdominal pressure increase, the abdominal contents get compressed and the diaphragm is pushed upward.[6]

Both the inspiratory and expiratory muscle function in a coordinated manner in a number of activities that an individual performs in day-to-day life. Activities like sneezing, coughing or defecation require the synchronous activity of these muscles to generate a large intrathoracic pressure. In coughing, a deep inspiratory effort is required. After this, the glottis closes and a very high intrathoracic pressure is generated due to the powerful contraction of the diaphragm and the abdominal muscles. The glottis than opens and this pressure is suddenly released and it leads to an explosive expiratory effort. This causes a very high flow and generates a shearing force in the airways. This helps in removing secretions and other foreign particles, which may be present in the airways.

RESPIRATORY MUSCLES—BASIC PHYSIOLOGY

Respiratory muscles generate pressure differences during the cycle of breathing, which allow ventilation to occur. It is important to remember that respiratory muscles differ from other skeletal muscles in certain key ways. Firstly, they are the only skeletal muscles on which life depends. Secondly, they are under both voluntary and involuntary control. Also, respiratory muscles contract mainly to overcome elastic and resistive loads. This is unlike other skeletal muscles, which cope mainly with inertial load. They are also by far the most extensively used skeletal muscles. The force generated by the respiratory muscles, as for any muscle, depends upon its level of excitation, the initial resting length and the mode of contraction.[12]

One important component in the functioning of the respiratory muscles is the length tension relationship. In a muscle, the active force developed is a function of the length of the muscle. As the length of muscle fibers decreases, its capacity to generate pressure also decreases. On the other hand, lengthening of a muscle fiber, up to a point, increases its capacity to generate force.[12] This concept is important to understand in relation to the diaphragm. In patients with COPD as the lung hyperinflates, the diaphragm is pushed down and the length of the muscle fibers decrease. This significantly decreases the efficiency of the diaphragm to generate force and thereby increases the work of breathing.

Whenever a muscle is stimulated, it contracts and generates a force. As the frequency of the stimulus increases, there occurs an associated increase in the force the muscle can generate. As the stimulus is further increased, the force that the muscle can generate continues to increase until it reaches a plateau and above this frequency the force does not increase.[5] This plateau is reached at a frequency above 50 Hz and this association between stimulus and the force that a muscle generates is known as force – frequency relationship. Another mechanical property, which is important, is the relationship between the force a muscle generates and the velocity of muscle fiber shortening. The greater the force a muscle generates, the slower the velocity of contraction. There is therefore an inverse relationship between the velocity of muscle contraction and the force generating capacity of a muscle.[6]

It has been shown that the respiratory system has been designed in such a way that after some time as the inspiratory demand increases, rather than increasing the force of contraction, newer inspiratory muscles of respiration get recruited. In this way muscle function is coordinated so that the respiratory muscles are always shortening at a velocity that will lead to optimum function.

EVALUATION OF RESPIRATORY MUSCLE FUNCTION

Assessment of respiratory muscle function should form a part of routine respiratory system diagnostic work-up. Dyspnea occurring when no other pulmonary cause is apparent may occur due to respiratory muscle weakness. Broadly, evaluation of respiratory muscle function would be indicated in two situations: (i) When clinical features suggest respiratory muscle weakness and (ii) if the patient is suffering from a disease where respiratory muscle weakness is known to occur. Respiratory muscle assessment is also being done where muscle weakness may affect other disease processes, as may occur with steroid therapy, prolonged mechanical ventilation and severe malnutrition.[13-16]

History and Examination

Breathlessness is the main symptom of patients with respiratory muscle weakness. In patient with generalized neuromuscular diseases, respiratory muscles are usually involved and these patients may show wasting and fasciculation of the limb muscles. Patients with significant diaphragmatic weakness classically complain of breathlessness when supine, or sitting or standing in water.[2] Breathlessness which occurs immediately on lying supine or on entering a swimming pool is very suggestive of severe diaphragmatic weakness. As the respiratory muscle weakness progresses, it lead to nocturnal hypoventilation and disturbed sleep. This leads to day time somnolence and impaired intellect.[17] Ultimately, ventilator failure and cor pulmonale develop. Patients with weakness of bulbar and expiratory muscle have poor cough and these patients have a higher chance of developing recurrent aspiration and pneumonia.

Physical examination may at times be helpful. Increase in respiratory rate may occur due to respiratory muscle weakness. Use of accessory muscles and intercostals recession may suggest respiratory distress and muscle weakness. Patients with diaphragmatic weakness or paralyses show a typical paradoxical inward inspiratory abdominal movement. Normally, as the diaphragm contracts during inspiration, the abdominal contents are pushed down and the abdominal wall moves outwards. In patients with diaphragmatic weakness or paralysis, during inspiration, the pleural pressure becomes more negative and the weak or paralyzed diaphragm gets sucked into the thoracic cage. This leads to the paradoxical inward abdominal movement during inspiration. This movement is better appreciated in the supine position.[3] These physical findings are usually only appreciated when diaphragmatic weakness has progressed to more than 75% and therefore significant respiratory muscle weakness may be missed on clinical examination.[18]

Imaging to Assess Respiratory Muscle Function

A plain chart radiograph may show an elevated hemidiaphragm and this may suggest hemidiaphragmatic paralysis. In patients with bilateral diaphragmatic paralysis, both hemidiaphragms are elevated and the X-ray may appear relatively normal.[19] Fluoroscopy is a commonly used test in suspected hemidiaphragmatic palsy and is positive in about 90% of cases.[5] An upward or cephalad movement of the diaphragm is seen. This test can be falsely positive and does not provide information about the extent of diaphragmatic weakness. A short sharp submaximal sniff during fluoroscopy is a useful maneuver to assess for diaphragmatic weakness.

Ultrasound has emerged as a useful tool to assess movement, thickness and zone of apposition of the diaphragm.[20] Besides this subpulmonary or subdiaphragmatic collections, traumatic rupture and pleural masses can also be detected.[21] It is also a safe method with no radiation exposure and is simple to perform. Ultrasound has also been used for assessing hemidiaphragmatic movements, zone of apposition and the thickness of the diaphragm.[22] Hemidiaphragmatic movement has been evaluated in normal individuals and in patients with underlying respiratory diseases. By this technique, the normal range of craniocaudal excursion of the posterior hemidiaphragm has been established and an acceptable reliability has been obtained in the terms of interobserver and intraobserver reproducibility. It has also been found to be a reliable quantitative as well as qualitative method for assessing posterior diaphragmatic excursions. Ultrasound has been also used to see the thickness and length of the zone of apposition with good results.[23] The thickness of the zone of apposition at different lung volumes has been measured. This measurement has shown good repeatability in most subjects although it may be difficult to perform in obese individuals.[23] Ultrasound has also been used to evaluate the thickness of the diaphragm in different neuromuscular and respiratory diseases.[22,24]

Function Testing

At times, conventional spirometry provides the first suspicion of respiratory muscle weakness. As spirometry is routinely done and easy to perform, it is often used to assess the severity, progression and functional consequence in patients with confirmed respiratory muscle weakness. Patients with inspiratory muscle weakness classically have low vital capacity, decreased Total Lung Capacity (TLC) and near normal Residual Volume (RV).[23] The Functional Residual Capacity (FRC) is also relatively preserved in patients with respiratory muscle weakness. Usually the total lung capacity is less markedly reduced than the vital capacity and therefore the RV/TLC ratio and FRC/TLC ratios are often increased.[23] A normal vital capacity makes respiratory muscle weakness highly unlikely. Diffusion capacity to carbon monoxide is reduced, but normal or raised when adjusted for volume and this helps to distinguish respiratory muscle weakness from alveolar disorders like pulmonary fibrosis.

In patients with diaphragmatic palsy, the vital capacity falls when the patient is supine, and this fall should be more than 25% to be definitely abnormal.[25] Regular monitoring of vital capacity is also useful in patient with progressive muscle weakness or paralysis, i.e. Guillain–Barré syndrome.[26,27] If the vital capacity falls below 50% from baseline, the patient may need ventilator support. It must be remembered that in patient with long-standing respiratory muscle weakness, vital capacity will also fall due to reduced chest wall and lung compliance, possibly due to microatelectasis.[5] Vital capacity maneuver is a patient-dependant maneuver and therefore, the result depends upon patient's motivation and ability. Moreover, a number of other diseases can lead to a decreased vital capacity. This test is therefore neither specific nor diagnostic.[28]

Flow Rates and Dynamic Spirometry

In patients with pure respiratory muscle weakness, airway resistance is normal. A decrease in both inspiratory and expiratory flow rates occurs in patients with respiratory muscle weakness. These flows are decreased more in the effort dependant part of the flow volume loop. The decrease in expiratory flow rates is less as compared to inspiratory rates and the ratio of maximum mid inspiratory flow rates to maximum mid expiratory flow rates, which is usually greater than one, is less than one in cases of respiratory muscle weakness.[23] However, a similar decrease can occur in extrathoracic upper airway obstruction. Flow volume loop shows a decrease at high lung volumes than at low lung volumes and peak flow is markedly decreased. As residual volume is approached, expiratory muscles cannot overcome the outward elastic recoil of the chest wall, flow rapidly decreases and ceases at high residual volume. Because of this, the descending loop of the flow volume curve tends to be convex rather than concave, with an abrupt drop off of flow at the end of expiration.[23]

Maximum Voluntary Ventilation (MVV) is also reduced.[5] This test is also done and in the past was recommended to assess respiratory muscle weakness. However, it is not a sensitive test and is not useful to diagnose respiratory muscle weakness.[5]

Oximetry

Monitoring overnight pulse oximetry may help in providing evidence to the severity of respiratory muscle weakness.[2] A normal nocturnal oximetry suggests that the muscle weakness is not severe enough to cause ventilatory failure. On the other hand, demonstration of nocturnal hypoventilation suggests severe respiratory muscle weakness, which may cause ventilatory failure. Patients with moderate-to-severe respiratory muscle weakness show fall in oxygen saturation during rapid eye movement sleep.[5] This fall in oxygen saturation is mainly due to hypopneas and these may appear to either central or obstructive or a mixture of both.[29] In patients with pure respiratory muscle weakness substantial nocturnal desaturation occurs only if respiratory muscle strength is less than one-third of normal.[2] As respiratory muscle weakness progresses hypercapnia starts occurring initially during sleep. Many of these patients may have coexisting respiratory disorders, which may also contribute to hypoventilation.

Mouth Pressures

These tests give a good estimate of global respiratory muscle strength. The tests most widely used to assess inspiratory and expiratory muscle strength are static Maximum Inspiratory Pressures (MIP) and static Maximum Expiratory Pressure (MEP) at mouth. These tests are simple to perform, fairly accurate, noninvasive and well tolerated by the patients. Also, normal values for MIP and MEP have been established in different ethnic groups.[30-33] Portable and inexpensive devices are now available, which allows one to measure MIP and MEP at beside, in the Outpatient Department (OPD) and in the Intensive Care Unit (ICU)[34] (Fig. 26B.1).

Both MIP and MEP are measured at different lung volumes so that the maximum muscle strength of the muscle can be measured. The length of the respiratory muscles and therefore their contractile force vary with lung volume. The force a skeletal muscle can generate depends on the force-velocity and force-length relationship (see section on respiratory muscle physiology above). The expiratory muscles are longer at high lung volumes and so expiratory muscles contractile force is highest at or near total lung capacity. Conversely inspiratory muscles are longer at low lung volumes and so inspiratory muscle force is greatest between functional residual capacity and residual volume.

Devices used to measure MIP and MEP measure inspiratory and expiratory pressures at mouth when the patient makes a maximum effort against a closed airway.

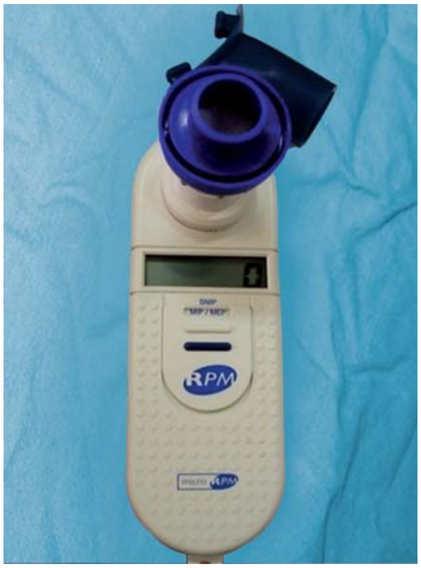

Fig. 26B.1: Simple portable device to measure mouth pressures and sniff nasal inspiratory pressure

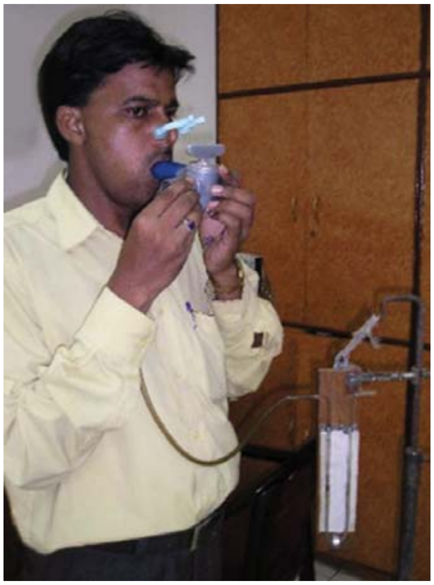

Fig. 26B.2: Traditionally used method to measure mouth pressure using a mercury manometer

Initially a mercury manometer was used to measure MIP and MEP (Fig. 26B.2), but this has been replaced by a pressure gauge, which is now used to measure the pressure (Fig. 26B.3). Lips are pursed inside a wide bore mouth piece. This contracts the facial muscles and prevents the cheeks from ballooning during expiration.[30,33] The inspiratory and expiratory pressure must be maintained for at least 1.5 seconds, so that the maximum pressure sustained for at least one second can be recorded. For

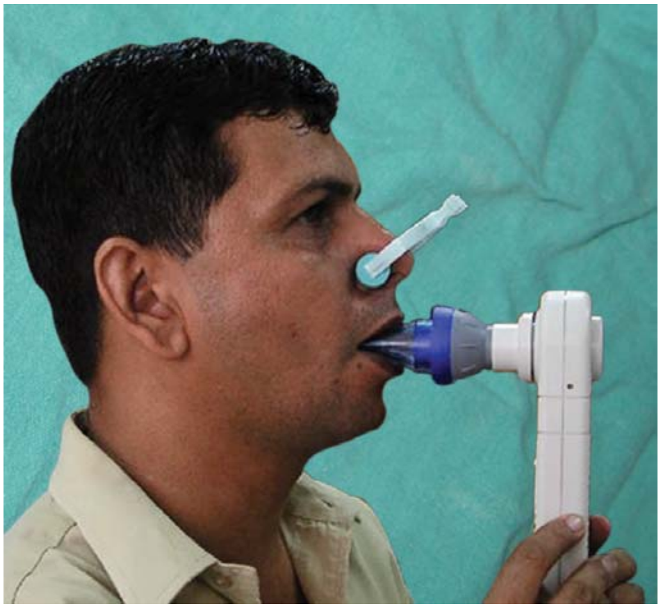

Fig. 26B.3: Pressure meter being used to measure mouth pressure

reasons explained above, to get the best readings of respiratory muscles strength, MEP is measured at or near total lung capacity and MIP between residual volume and functional residual capacity. In females, MIP and MEP are about 65% to 70% less than that of males. Over the age of 50 years in both sexes, the pressure values are about 85% to 90% of that for younger adults. Also, a much greater degree of intrasubject variability in pressure is present as compared to variation in spirometry.

Like the vital capacity, a normal or high MIP (more than 80 cm of H_2O) rules out clinically significant respiratory muscle weakness.[2] Both MIP and MEP are subject dependant and at times it is difficult to ensure that the patient is making a truly maximum effort. Therefore, patient's cooperation is very important. A low value may, therefore, be due to poor effort and may underestimate the strength of the respiratory muscles. As this test is easy to perform and normal values are available it is widely used to rule out respiratory muscle weakness. Serial measurements over time may give valuable information about progression or improvement in muscle weakness in patient with chronic neuromuscular disease. Also, MIP is useful to assess respiratory muscle strength in the ICU in patients on mechanical ventilator to determine fitness to wean off the ventilator. Patients with an MIP less than in 20 cm H_2O are usually unfit for a weaning trial.[35]

Nasal Pressures

Another method used to assess respiratory muscle strength is by doing the sniff test.[36,37] A sniff is an inspiratory maneuver, which is short and sharp in performed through one or both unoccluded nostril. During a sniff, there occurs a sharp contraction of the diaphragm and other inspiratory muscles. Sniff is a natural maneuver, is simple and noninvasive and may patients find it easy to do. It has been shown that in normal subjects, the pressure developed in the esophagus during a sniff closely relates to the pressure in the nasopharynx, mouth and nose.[38] Therefore, measurement of the Sniff Nasal Inspiratory Pressure (SNIP) provides a good estimate of inspiratory muscle strength. Normal value of SNIP have been established and it has been evaluated in patients with COPD and interstitial lung disease.[39,40]

The tests consists of asking the subject to perform a short sharp maximal sniff through one unobstructed nostril while measuring nasal pressure through a catheter wedged in the contralateral nostril (Fig. 26B.4). Various methods for wedging and occluding the nostril with a small tube are used. These include foam, rubber bung and dental molding material. This test is easy and natural and allows patients to activate inspiratory muscles completely. This test is also relatively reproducible and has a smaller range of normal values than mouth pressures.[37,38] Simple portable devices are available for SNIP recording and this test can now be done at the bedside.[41]

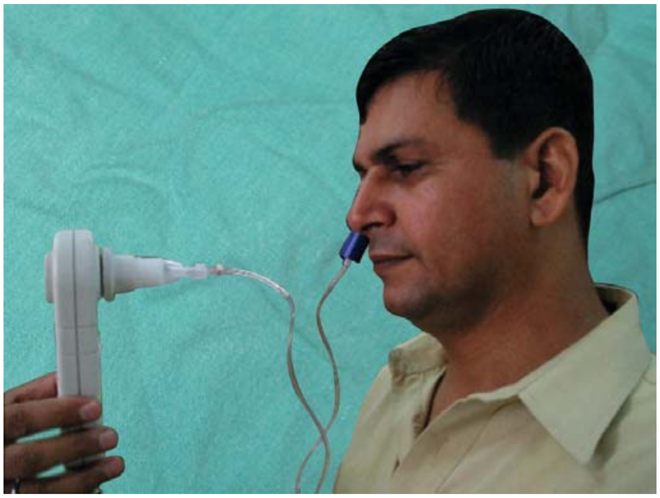

Fig. 26B.4: Sniff nasal inspiratory pressure being measured using a catheter and a nasal bunge to occlude one nostril

Invasive Tests

i. Transdiaphragmatic Pressure

Sometime noninvasive tests do not help in confirming the absence of respiratory muscle weakness and at times a more accurate estimation of the degree of muscle weakness is needed for treatment purpose in patients with underlying respiratory muscle weakness. In such situations tests, which are more precise, but invasive and where patients' own effort is not required, are used. These tests require the introduction of two small latex balloons, which are sealed over a catheter into the esophagus and stomach. These balloons are thin walled, usually 5 to 10 cm long and have a 3.5 to 5 cm perimeter.[23] The catheter is about 70 to 100 cm long. The catheter is attached to a transducer, which records the pressure. Using local anesthesia, these small esophageal and gastric balloons are introduced through the nose and gradually passed through the phyranx into the esophagus. One catheter is positioned at the lower end of the esophagus (esophageal balloon) and the other is positioned in the stomach (gastric balloon). A very small amount of air is introduced into these balloons. One balloon lies just above (reflects pleural pressure) and the other just below the diaphragm (reflects abdomen pressure).[23] This allows one to measures the pressure difference across the diaphragm when it contracts and therefore the transdiaphragmatic pressure (Pdi) can be measured.

ii. Maximum Transdiaphragmatic Pressure (Pdi max)

Measurement of Pdi max gives an idea of the strength of the diaphragm. Transdiaphragmatic pressure is calculated as the difference in the Gastric Pressure (pga) and the Esophageal Pressure (Pes) measured when the subject makes an isotonic contraction during a maximal voluntary effort. The transphragmatic pressure will vary with lung volume and should therefore be recorded at a known lung volume (usually FRC). Normal value for Pdi max and in patients with different lung diseases have been established.[42]

iii. Transdiaphragmatic and Esophageal Pressure During Sniff

Sniff is easy to perform and most subjects are easily able to perform a maximal sniff effort. With the gastric and esophaged balloons in place, the subject is asked to perform a maximum sniff at FRC without using a nose clip.[2] The Sniff Transdiaphragmatic Pressure (Sniff Pdi) is recorded. Usually the patient is asked to perform a number of these maneuvers till three reproducible tracings are obtained. Sniff Pdi has been studied in normal and in different diseases. It has a narrow normal range and better between day coefficient of variation than MIP.[37]

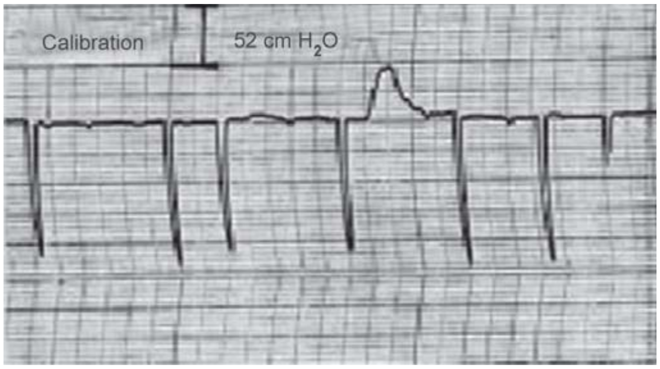

Fig. 26B.5: Tracing of sniff esophageal pressure recorded in a patient using an esophageal balloon catheter. Patient has performed multiple sniff maneuvers. The upward positive wave is due to swallowing

Studies suggest that clinically useful information about diaphragmatic strength can be obtained by using a single esophageal catheter and measuring Sniff Esophageal Pressure (Sniff Poes)[43]. A single esophageal catheter is routinely used in many respiratory laboratories for measuring lung compliance. Esophageal pressure is measured, with a pressure transducer, while the patient makes a short, sharp, maximal sniff. This esophageal pressure during a sniff (Sniff Poes) closely relates to Sniff Pdi and is simpler to do (Fig. 26B.5).

All these tests, i.e. Pdi max, Sniff Pdi and Sniff Poes, are useful, accurate and reproducible tests. They provide reliable assessment of the diaphragmatic strength. However, like previous tests they also are dependent on patient's cooperation and low values become difficult to interpret at times.

iv. Tests Where Subject's Cooperation Not Needed

Phrenic nerve stimulation: The diaphragm is innervated by the phrenic nerves only. Thus stimulating the phrenic nerve provides a unique way of assessing diaphragmatic function without the cooperation of the patient. Besides pressure measurement, phrenic nerve stimulation also allows to record electromyogram of the diaphragm and phrenic nerve conduction time.[44] Phrenic nerve stimulation super imposed on a naturally occurring or voluntary contraction is an important research tool and provides information about the maximal voluntary pressure that the diaphragm can generate.[45]

Electrical stimulation: Electrical stimulation of the phrenic nerve can be done in the neck and the diaphragmatic contraction can be measured by the esophageal and gastric balloons.[23] The contraction, which is the twitch transdiaphragmatic pressure (twitch Pdi) has the advantage that it does not need patient's motivation or cooperation. Both unilateral and bilateral electric stimulation of the phrenic nerve can be done. The phrenic nerve is usually located just beneath the posterior border of the sternocleidomastoid muscle at the level of the cricoid cartilage. Precise location of the nerve is required for electrode placement and to achieve this, repeated stimulation near the site is frequently required. Once the nerve is identified, the spot is marked and the orientation of the electrode in the neck is observed by the operator.[23] The operator usually stands behind the seated subject and the current intensity is increased to obtained supramaximal stimulation. The procedure is usually done on each side separately and after that bilateral electrical stimulation is applied and twitch Pdi is recorded with the esophageal and gastric balloons. Twitch Pdi has been measured in normal subject and in patients.[46,47] This test can be uncomfortable as the stimulus intensity is increased to achieve supramaximal stimulation. Also, sometimes it is difficult to locate the exact site of the nerve and reliable supramaximal stimulus is not obtained. This test is useful when there is severe weakness or the results of the previous tests are not definite as the patient is unwilling or unable to cooperate.

Magnetic stimulation: It has been known for long that magnetic fields can stimulate the nervous structures.[48] The last decade has seen the extensive use of magnetic stimulation in neurology.[49] Magnetic stimulation by a magnetic coil creates brief and intense magnetic field.[23] This field is only mildly hampered by structures on the surface of the body like skin and bones. It therefore reaches the deeper nervous structures and the rapidly changing magnetic field causes current to flow in the nervous tissue within the field.[50,51] This in turn causes the muscle to contract. Magnetic stimulation overcomes a lot of problems associated with electrical stimulation.[52,53] It is relatively painless and easy to apply in a clinical setting. By placing a circular magnetic over the cervical phrenic nerve routes one can achieve supramaximal bilateral phrenic nerve stimulation once this coil is activated.[54,55] The magnetically measured Pdi is slightly greater than the electrical Pdi possibly due to the activation of accessory muscle, which may get activated due to the spread of the magnetic field.[2]

For the assessment of respiratory muscle function, bilateral phrenic nerve stimulation can be achieved by stimulating the phrenic nerve roots in the cervical spine.[54,55] More localized phrenic nerve stimulation can be achieved by using a figure of eight-shaped magnetic coil in the neck. This coil can be used unilaterally for unilateral stimulation of the phrenic nerve or bilaterally for bilateral phrenic nerve stimulation.[56,57] This allows easy and accurate assessment of hemidiaphragmatic function. Bilateral anterior stimulation also has the advantage that it can be done in supine position.[56,57] Respiratory muscle assessment using magnetic stimulation is now done as an OPD procedure, in the ward and even in an ICU setting.[58] This has largely replaced and electric stimulation has become well established in clinical practice.

Magnetic stimulation of the respiratory muscle is being increasingly used to assess respiratory muscle function and endurance.[56,59] The role of abdominal muscle and the pressure changes that occur during abdominal muscle stimulation is being better understood.[60] Also, the mechanism of diaphragmatic fatigue, cough, etc. are also evaluated.[56,61,62]

Electrophysiological Assessment of Respiratory Muscles

Electromyography (EMG)

Electromyography has traditionally been used to assess various aspects of skeletal muscle function. Stimulation of the phrenic nerve causes the diaphragm to be activated and the electrical signal generated by this activation is recorded.[63] Recording EMG of the respiratory muscles can help to assess the level and pattern of activation of these muscles. This helps in the diagnosis of neuromuscular diseases and when combined with other tests, helps to assess the efficacy of the contractile function of the muscle. To record EMG of the diaphragm, electrodes can be placed at different sites. Surface electrodes can be placed in the neck, over the chest wall muscles or next to the area of apposition of the diaphragm on the chest wall. Electrodes wound around a small catheter can be swallowed and placed in the lower esophagus to measure a more pure crural diaphragm EMG. Electrodes can also be inserted into the respiratory muscle of interest using wire, needles or hook electrodes.

Surface electrodes are commonly used because they are noninvasive, easy to apply and a large number of motor units can be assessed. Surface electrodes have been used to assess activity of the diaphragm, scalene, intercostals, abdominal muscles and accessory muscles. The electrodes are placed over or as close as possible to the muscle to be evaluated. The site is determined by palpation and knowledge of the surface anatomy of the respiratory muscles.

Diaphragmatic EMG can be obtained by needle electrodes introduced with reasonable safety through the 10th intercostals space in the mid axillary line. Placement of surface electrodes in the 7th, 8th and 9th intercostals space can also be used to record diaphragm EMG. Esophageal electrodes are used more for research purpose. They provide a more accurate and pure diaphragm EMG. Electromyography is useful in distinguishing neuropathic and myopathic diaphragmatic dysfunction. It may also help in detecting diaphragmatic fatigue.

Respiratory Muscle Endurance

Muscle endurance can be defined as the ability to sustain a specific muscular task over time.[23] Although respiratory muscle strength and endurance appear to be closely linked, there are many conditions where the endurance of the respiratory muscles cannot be predicted by measuring maximum pressures or maximum ventilator capacity. For example, certain respiratory muscle training protocols used in normal individuals and in patients has a greater effect on endurance than on muscle strength.[64,65] Similarly some asthmatic patients show an inherent elevation in endurance properties as a faction of strength.[66] Also, patients with COPD or those on acute steroid treatment show significant reduction in endurance properties relative to strength.[67,68] Therefore, measurement of endurance of the respiratory muscles can have important clinical implications. It may also have an important utility in assessing the efficacy of a rehabilitation program. Unfortunately no uniformly accepted and simple method exists for the estimation of endurance.

Endurance may be measured as ventilator endurance or endurance to an applied load.[23] Traditional approach for evaluating ventilator endurance has been to measure the Maximum Sustainable Ventilation (MSV), i.e. the maximum ventilation that can be maintained for 10–15 minutes. Maximum sustainable ventilation is usually expressed as a fraction of maximal voluntary ventilation (MMV). Normal subjects can achieve a MSV, which is 60% to 80% of MMV.[69] Various techniques have been used to calculate MSV. The maximum effort technique requires the subject to breath at a ventilation of approximately 70% to 90% of their MMV using a visual feedback from either a spirometer or an oscilloscope.[23] Another method that has been used utilizes a 10% incremental increase in target ventilation, every three minutes, beginning at 20% of maximum voluntary ventilation until the subject cannot sustain the target ventilation. MSV is calculated from the last 10 breaths of the last minute of the highest target ventilation. Tests for MSV have been found to be exhaustive and time consuming and are largely impractical.

Various devices have been used to assess endurance against an applied load. Early methods utilized orifice type flow resistance applied to the inspiratory circuit, but these have been replaced by threshold resistive loading devices, which make it possible to more accurately control the pressure the subject inspires against, independent of flow.[23] Inspiratory threshold devices have also been used to test endurance.[23,70,71] Technique involves inspiring through a device that contains a weighted plunger. To initiate inspiration, enough pressure must be generated to lift the plunger out of the socket. Thereafter inspiration remains constant for the entire inspiration.

A negative pressure device and a three-minute incremental protocol has also been described to measure endurance and fatigue.[61,72] The ability to sustain such a breathing effort during an endurance test depends upon the force and the duration of the inspiratory muscle contraction. It has been demonstrated that intense diaphragmatic contractions of brief duration can be sustained for as many breath as could less intense diaphragmatic contractions of brief duration that occupied a larger fraction of breath.[23] Therefore, the Tension Time Index of the Diaphragm (TTIdi) is calculated to predict fatigue and is a better marker than either contractile force or duration of contraction. TTIdi is the product of the contractile force and duration and contraction. Force is expressed as Pdi breath/Pdi maximum. The duration of contraction is the inspiration duty cycle (this is TI/TTOT, i.e. the duration of inspiration divided by the duration of a complete breath). It has been shown that the human diaphragm becomes fatigued when the TTI di exceeds 0.15.

CONCLUSION

Respiratory muscles are essential for life. Their assessment and early detection of weakness becomes important. The diaphragm, which is the main muscle of respiration, is unique that it can be assessed by the volume displaced (spirometry), pressure generated (muscle strength) and by the Electrical Activity of the Muscle (EMG). Many different tests have therefore been used to assess diaphragm function. Tests for diaphragmatic endurance and fatigue are also used. Besides respiratory diseases, many systemic illnesses and disorders cause weakness of the respiratory muscles and their assessment becomes important in these diseases.[14,16,68,73,74] It is therefore important to know when to suspect respiratory muscle weakness in a given patient and how best to test for such weakness.

Respiratory Disability and Preoperative Evaluation

Gyanendra Agrawal, D Gupta

INTRODUCTION

Both disability assessment and preoperative evaluation focus on the accurate assessment of the functional state of the respiratory system. The initial part of this chapter is intended to provide a framework for the evaluation of impairment and disability caused by respiratory diseases, including common occupational and environmental respiratory diseases. The later part focuses on a comprehensive clinical assessment and appropriate standardized tests, to objectively assess the risks and the outcomes of patients with lung disease undergoing specific surgeries.

EVALUATION OF RESPIRATORY DISABILITY

The ability of an individual to take part in the gainful employment and activities of daily living are profoundly affected by the respiratory impairment. The common reasons for the evaluation of impairment/disability are to assess fitness for a particular job, to decide compensation on a litigation following a workplace injury, and to assess the eligibility for government entitlement programs in certain countries.

Evaluating physicians generally fit into two categories such as treating (personal) physician and Independent Medical Examiner (IME). Treating physicians know better about health of their patients, however, they may be biased. IME, generally appointed by the referring agency, is supposed to provide an unbiased objective evaluation. Evaluation of impairment/disability is a multistep process in which the physician assesses impairment, the award of benefits is decided at an administrative level. Although the physician's input is important, the patient must understand that the physician does not have control over the acceptance of claims or level of benefits awarded.

Impairment, Disability and Handicap

Impairment is defined as "a loss, loss of use, or derangement of any body part, organ system or organ function." This is purely a medical condition that objectively measures any loss or abnormality of psychological, physiological, or anatomical structure or function.[1,2]

Disability is a term that indicates the total effect of impairment on a patient's life. It is affected by diverse factors such as age, gender, education, economic and social environment and energy requirements of occupation. Thus, two people with an identical impairment may have different disability.[1,2]

Handicap is "the disadvantage for a given individual, resulting from impairment or disability, which limits or prevents fulfilment of a role that is normal (depending upon age, sex, and social and cultural factors) for that individual."

CLINICAL METHODS OF EVALUATING IMPAIRMENT

Accurate assessment of respiratory impairment requires a medical diagnostic evaluation. Decreased lung functions may result totally or in part from nonrespiratory diseases either directly (e.g. neuromuscular diseases, arthritis of the spine) or indirectly (e.g. congestive cardiac failure). Moreover, the accurate diagnosis and staging of the disease is the basis for sound prognosis and medical prescriptions, which later may bear importantly on the determinations of disability and impairment. The evaluation of respiratory diseases must include a chest radiograph, in addition to indicated laboratory tests.[2]

History

The most common symptoms that lead to pulmonary disability evaluation are dyspnea, cough and wheezing. Dyspnea or shortness of breath is a distressing sensation of difficult, labored or unpleasant breathing. Dyspnea is entirely subjective and fairly sensitive, but not specific, symptom. In all patients, an attempt should be made to rate the severity of the patient's dyspnea by the means of a scale or classification scheme, such as that suggested by the Medical Research Council (MRC).[3] In the context of disability evaluation only the chronic forms of cough (i.e. lasting for more than four weeks) and sputum production are relevant. It is difficult to quantitate the severity of cough and therefore, it is not easy to integrate them into a system of progressive gradation of disability. A history of wheezing may provide important clues during disability evaluation. The temporal correlation of the onset of wheezing, as well as its association with the workplace (or with particular exposures), may help to identify a specific cause of impairment. Wheezing that occurs primarily on workdays and improves during weekends or during vacations is highly suggestive of work-related asthma.

A comprehensive medical history, including the documentation of hospitalizations, allergies and medications, should be obtained, so conditions other than respiratory diseases that contribute to or likely to modify any impairment can be identified. A detailed history of the applicant's employment in chronologic order is required for both attribution and disability evaluation purposes. This history should include even part-time jobs and hobbies. History of exposure to specific respiratory agents at the workplace, like dusts, fumes and vapors should prompt further questioning to clarify the timing, duration and dose of exposure when possible, and the use of respiratory protection. Many work-related abnormalities resemble other diseases and cannot be diagnosed correctly without a validated exposure history. Presence of similar complaints or diseases also in coworkers, is helpful in establishing an occupational etiology.

Inquiries should be made into avocational activities to uncover any potential contributing exposure (e.g. pigeon breeding). An environmental exposure history should include a discussion of potential environmental triggers that include pets in the household, exposures to birds or other organic antigens, such as molds, as well as seasonal or temporal variability of symptoms. Smoking can be the primary cause or a major contributing factor to many respiratory diseases; therefore, a detailed smoking history should be obtained. This includes the age at which the patient started to smoke, estimates of both the average and maximum amount of tobacco smoked per day, whether and when smoking was stopped, as well as second-hand smoke exposure. The cumulative dose of cigarette smoke exposure should be characterized in terms of pack-years (i.e. the number of packages smoked per day multiplied by the number of years of smoking).

Physical Examination

A physical examination that is primarily focused on the cardiopulmonary system should be performed. The patient also should be evaluated for clinical evidence of right heart failure associated with advanced and chronic respiratory disease (cor pulmonale). The physical examination is probably more useful for detecting the signs of nonrespiratory organ system dysfunction that could be contributing to a disability than for characterizing the level of respiratory impairment.

Imaging Studies

The chest radiograph is the most widely used element in the clinical evaluation of patients with respiratory disease. It is more useful in determining the etiologic diagnosis than the level of impairment, because the correlation between radiographic abnormality of the chest and physiologic dysfunction is imperfect, especially among patients with obstructive lung diseases. An asthmatic patient with severe, partially irreversible airflow obstruction may have only minimal abnormality of the chest radiograph. Conversely, patients with a significant amount of bullous emphysema may not have a comparable degree of airflow limitation.[4]

Among patients with pneumoconioses (inorganic dust-related pulmonary interstitial diseases, such as asbestosis, silicosis and coal workers' pneumoconioses), the chest radiographic findings are very important. In fact, the International Labor Organization (ILO) has devised a classification scheme for the standardized interpretation of chest radiographs to objectively characterize and communicate the extent of radiographic abnormalities in the pneumoconioses.[5]

Computed tomography of the chest is a more sensitive tool than plain radiographs in detecting both parenchymal and pleural abnormalities. They offer considerable insight into the precise anatomic changes that accompany a disease state, but offer little to the evaluation of physiologic impairment. However, there are no recommendations at present for CT-screening of populations at risk for occupational interstitial lung disease.

Pulmonary Function Testing

Simple pulmonary function tests like spirometry and diffusing capacity measurements are the most commonly used objective measures of respiratory limitation for disability assessment. The equipments used for these tests are widely accessible and adequate standards for repeatability and reproducibility can be easily met. Both these tests should be performed carefully according to the ATS/ERS guidelines.[6,7] Spirometry can distinguish obstructive from restrictive lung physiology and provide the quantification of the degree of pulmonary dysfunction. On the basis of FVC, FEV_1, and diffusing capacity, classification of degree of respiratory impairment can be made. The diffusing capacity has particular usefulness in the evaluation of restrictive ventilatory defects and is more sensitive than lung volume measurement as a screening tool for patients at risk for pneumoconiosis.[8]

Arterial Blood Gas Analysis

Arterial blood gas studies are rarely used as a criterion of impairment and should be reserved for selected patients. Because of the variability of arterial blood gas measurements even in stable patients, arterial hypoxemia should be documented by a minimum of two measurements, at least four weeks apart. Resting arterial hypoxemia is considered as a "modifying condition" in the ATS statement; for example, in a patient whose spirometry and DL_{CO} results straddle the border between the two categories of impairment, the presence of a low arterial PaO_2 can justify a rating of the higher category of impairment.[2]

Cardiopulmonary Exercise Testing

Majority of the patients being evaluated for respiratory disability do not require exercise testing because there is a good relationship between FEV_1 and DL_{CO} and oxygen consumption and work capacity.[9,10] The physician should consider Cardiopulmonary Exercise Testing (CPET) only when there are grounds for believing that the routine tests have underestimated the impairment. The aim of exercise testing in such cases is to determine first, whether or not the person is significantly impaired, and secondly, whether the cause of impairment is due to respiratory disease or some other cause.[2] Because of the later need, the testing must at a minimum include the measurement of Ventilation (V_E), maximal oxygen consumption (VO_2 max) and anaerobic threshold. The measurement of oxygen consumption during CPET is considered to be the "gold standard" assessment of the subject's ability to perform work[4] (See Chapter 26A for CPET).

Bronchoprovocation Testing

Bronchoprovocation testing is an important method in the assessment of impairment and disability in the cases of occupational asthma, because routine pulmonary function testing performed between attacks may not reveal the abnormality. The presence of bronchial hyperreactivity may have significance in judging ability to continue certain types of employment.

DISEASE-SPECIFIC IMPAIRMENT ASSESSMENT

Asthma

Evaluation of impairment in the setting of asthma is a problematic aspect of disability assessment, since asthma is a disorder characterized by variability over time, with airflow obstruction that may revert toward normal, either spontaneously or as a result of medication administration. On the day of evaluation, patient's lung function may not show an accurate reflection of his usual condition, but may be atypically bad or atypically good.[4] Patients with history that is suggestive of asthma and have normal spirometry in the absence of medication for asthma, may be tested for airway hyperresponsiveness with nonspecific bronchodilator challenge.

Workplace exposures frequently exacerbate an underlying asthmatic condition (work-related asthma) or cause sensitization of the respiratory tract to materials found uniquely in the workplace (occupational asthma). Occupational asthma is the most frequently reported occupational lung disease in the industrialized world. It is important to distinguish immunologic occupational asthma from irritant-induced asthma, where continued work may be possible, if irritant exposures are reasonably controlled. Evaluation of impairment in patients with occupational asthma is almost similar to that for patients with atopic asthma. In addition to the pharmacotherapy, nonpharmacologic interventions must be addressed such as the control of environment triggers, patient and family education.[11]

Pneumoconiosis

A variety of inorganic dust exposure produces pulmonary fibrosis (e.g. asbestosis, silicosis and coal worker's pneumoconiosis) or both granulomatous disease and fibrosis (e.g. beryllium), each with fairly characteristic radiographic appearances. The diagnosis of pneumoconiosis is associated with an increased risk of future impairment, despite normal lung function at the time of testing, because further exposure to the causative agent may increase the risk of progression. Therefore, the recognition of radiologic manifestations of these diseases should prompt removal from mining employment, particularly in relatively young individuals. Such a prohibition is not obviated by showing that current exposure is within legally permissible limits, because such limits are not presumed to provide adequate protection for persons who already manifest the disease.[2]

Hypersensitivity Pneumonitis

With hypersensitivity pneumonitis, continued exposure to the offending agent is likely to lead to either acute attacks or insidious progression of disease, depending on the dose of exposure. Therefore, patients with hypersensitivity pneumonitis should be considered 100% impaired on a permanent basis for any job that involves future exposure to the causative agent.

Obstructive Sleep Apnea

Only some individuals with sleep apnea develop a functional impairment that affects work activity. In severe cases, it can result in the deterioration of daytime cognitive performance, which may interfere with work activities that require constant vigilance like vehicle and machine operators. The development of cor pulmonale indicates 'severe' impairment.[2]

Lung Cancer

Patients with lung cancer are presumed to be severely impaired for at least 1 year following diagnosis, even if surgical resection appears to have been successful in curing the disease.

DISABILITY EVALUATION

Disability evaluation is the determination of the impact of impairment on an individual's ability to meet the demands of his or her own life. Disability evaluation has a broader focus than impairment because factors like the essential requirement of a job, specific tasks, educational level of the individual, individual skills, and potential for retraining must be taken into consideration in determining a specific individual's disability. The American Medical Association (AMA) has developed guidelines for assessing physical impairment that are widely accepted by governments and legal systems as the standard of evaluation for loss of physical function.[12]

Varying percentages of lost function are grouped into four severity classes: Class one constitutes 0% functional loss (for instance, an observable abnormality caused by an anatomic variation); class two indicates that there is objective evidence for a 10% to 25% impairment of the whole person as result of organ dysfunction; class three indicates a 26% to 50% impairment of the whole person; and class four is 51% to 100% impairment of the whole person.

According to the AMA Guides, impairment rating requires that the evaluator first recognize that an abnormality is present, then identify the cause of the abnormality and objectively evaluate the severity of deviation from normal function, and finally, translate the severity of dysfunction into a numerically based classification that estimates how much of an effect the organ dysfunction has on the individual's ability to carry on the activities of daily living. Other steps that may be difficult for the evaluating physician are the work relatedness of the impairment (attribution) and the percentage of the total impairment due to work-related causes (apportionment). Regardless of the evaluating physician's opinions, the final decision concerning the level of disability is made administratively by the responsible agency after the consideration of nonmedical factors.

The evaluation of respiratory disability/impairment is a multistep process. Knowledge of these components of disability evaluation will help physicians to better serve their patients and supply appropriate data to the adjudicating system. Different programs under the social security systems in various countries provide financial and rehabilitative benefits to disabled individuals. However, such programs or specific entitlement systems are lacking in this country. With the introduction of such programs, the community will be better served, ultimately contributing to the growth of nation.

PREOPERATIVE EVALUATION OF RESPIRATORY SYSTEM

Pulmonary physicians are often requested to do the preoperative evaluation of patients by various surgical departments. The goals of this consultation are to estimate the risk of postoperative pulmonary complications, to optimize the patient's condition, and to propose strategies to decrease the postoperative pulmonary complications. The second part of this chapter is an attempt to encompass all aspects of preoperative pulmonary evaluation prior to both thoracic and nonthoracic surgeries. It focuses the approach to risk stratification based on patient- and procedure-related risk factor analysis, detailed preoperative pulmonary evaluation, and strategies to reduce postoperative pulmonary complications.

Pulmonary Physiology in the Postoperative Period

The knowledge of changes in pulmonary physiology is mandatory to understand the mechanisms of various pulmonary complications that occur in the postoperative period, since many postoperative respiratory complications are related to exaggerations of the expected postoperative changes in pulmonary function that occur as a result of the surgery itself, anesthesia, or various pharmacologic interventions.

The pulmonary functions in the postoperative period are characterized by moderate-to-severe reductions in Vital Capacity (VC) and smaller reductions in Functional Residual Capacity (FRC). While the Forced Expiratory Volume in 1 Second (FEV_1) is decreased, the ratio of FEV_1 to the forced vital capacity (FEV_1/FVC %) remains unchanged, indicating that the overall pattern of pulmonary function abnormalities is restrictive. A significant reduction with up to 70% decrease in VC and up to 50% decrease in FEV_1 and FRC is seen, leading to a high risk of atelectasis and hypoxia, especially in the first 24 hours. This severe reduction in lung function is seen more often with thoracic and upper abdominal procedures than with surgery involving the lower abdomen or extremities; and it gradually recovers within three weeks.[13] Reductions in other lung volumes, including Total Lung Capacity (TLC), Inspiratory Capacity (IC), Expiratory Reserve Volume (ERV), and Residual Volume (RV) have also been noted.[14] The proposed mechanisms for the reduction in lung volumes consist of the postsurgical pain and associated muscle splinting, which impair lung mechanics; and the diaphragm dysfunction.

The reduction of FRC is of major physiological significance postoperatively, since the decrease of FRC below the Closing Capacity (CC) leads to the closure of the alveolar units causing atelectasis. FRC is the lung volume at the end of a normal tidal expiration; and CC is the lung volume at which small airways in the lung bases begin to close during expiration because of a reduction in airway radial traction. When CC exceeds FRC, lung volume fails to increase sufficiently during tidal breathing to open all the airways and, consequently, some alveolar units remain closed. This creates an area of low ventilation relative to perfusion, which is the main mechanism of hypoxemia in postoperative patients. Elderly patients, smokers and COPD patients are at higher risk of getting such complications since the closing capacity is increased in these subset of patients.

Diaphragmatic dysfunction is an important factor, which contributes to the postoperative reduction in lung volumes. Postoperative pain, spasm and paralysis are all known to reduce diaphragm function, although relief of pain does not completely restore function. Rather, diaphragmatic dysfunction has been found to persist even with adequate pain relief.[15] Decreased central nervous system output to the phrenic nerves, possibly as a result of inhibitory reflexes arising from sympathetic, vagal or splanchnic receptors is the proposed mechanism of diaphragmatic dysfunction.

Postoperative hypoxemia is a quite common event and prophylactic oxygen therapy is routinely given to all patients undergoing thoracic and upper abdominal surgeries. The underlying mechanisms are multiple and are largely related to the residual effects of the anesthesia. This includes ventilation-perfusion mismatch, alveolar hypoventilation, anesthetic-induced inhibition of hypoxic pulmonary vasoconstriction, right-to-left shunting, and depressed cardiac output. Micro-thromboemboli, altered FRC-CC relationships and increased dead space ventilation due to rapid shallow breathing are other mechanisms contributing to postoperative hypoxemia. Respiratory depression either due to the anesthetic agents or narcotic drugs given for postoperative analgesia is a common feature of the postoperative period. These drugs reduce the ventilatory response to hypercapnia and hypoxia, resulting in decreased tidal volume and thereby increasing $PaCO_2$.

Several lung defense mechanisms are compromised after surgery, contributing to an increased risk of pulmonary infection. Ciliary damage from endotracheal intubation and inhalation of dry gases; and reduced tracheal mucus velocity leads to significantly reduced mucociliary clearance. Ineffective cough reflex due to postoperative pain, excessive use of narcotics or altered lung mechanics contributes to the retention of secretions and atelectasis.

Physiologic Changes After Thoracic Surgery

Resection of pulmonary tissue for various indications leads to a number of physiologic changes. Vital capacity decreases by about 15% after lobectomy and 35% to 40% following pneumonectomy.[16] The decrease in lung function is usually less than expected from the number of segments removed, suggesting that the disease had already decreased the function of the resected lung and/or that expansion of the remaining lung had occurred. Serial studies have shown that FEV_1 decreases within the first several months following lung cancer resection, but tends to recover to a small extent by six months after surgery.[17] The lung becomes stiffer and elastic recoil pressure and transdiaphragmatic pressure at TLC increases after thoracic surgeries. Maximum effort tolerance decreases after pneumonectomy with a normal pulmonary artery pressure at rest and an increase in pulmonary artery pressure and in pulmonary vascular resistance on effort, compared to preoperative values.

Lung Volume Reduction Surgery (LVRS) does not affect the postoperative pulmonary arterial pressure at rest or during exercise.[18] The patients also develop the decrease in arterial oxygen saturation on effort after pneumonectomy, possibly due to the absolute decrease in diffusing capacity. The patients also develop a decrease in oxygen consumption, cardiac output, stroke volume and heart rate at maximum exercise, and they were not able to achieve their preoperative maximal workload.[16] The changes seen after lobectomy are almost similar to the changes seen after pneumonectomy, but the differences are less pronounced.[19]

POSTOPERATIVE PULMONARY COMPLICATIONS

Postoperative pulmonary complications are at least as common as are postoperative cardiac complications and contribute similarly to morbidity, mortality and the length of stay.[20] Pulmonary complications may even be more likely than cardiac complications to predict long-term mortality after surgery.[21] A number of definitions have been proposed for postoperative pulmonary complications. A practical and clinically relevant approach is to include only those complications that contribute directly to morbidity or prolonged length of stay,[22] which will exclude minor complications such as fever and productive cough. Included are the clinically important postoperative pulmonary complications, which are pneumonia, atelectasis, bronchospasm, respiratory failure with prolonged mechanical ventilation, and exacerbation of underlying obstructive lung disease (Table 27.1). The reported incidence of these complications ranges from 5% to 90% depending on the variability of the definitions used. In general, pulmonary complications associated with thoracic surgeries are more common and more severe, as compared to nonthoracic surgeries. The mechanisms of postoperative impairment in lung function are multiple, interactive, and at present, incompletely understood.

TABLE 27.1: Postoperative pulmonary complications

*Nonthoracic Surgery**	*Thoracic Surgery*
Atelectasis	Bronchopleural fistula
Pneumonia and tracheobronchitis	Empyema
Respiratory failure with prolonged MV	Mediastinitis, osteomyelitis of sternum
	Phrenic nerve damage
Exacerbation of COPD	Anastomotic leak during esophagectomy/gastrectomy
Thromboembolism	

*May be associated with thoracic surgeries also.
MV: Mechanical ventilation; COPD: Chronic obstructive pulmonary disease

Risk Factors for Postoperative Pulmonary Complications (Table 27.2)

A number of risk factors have been associated with the development of postoperative pulmonary complications in various studies. In this chapter, patient- and procedure-related risk factors are discussed separately.

Patient-Related Risk Factors

The most important patient-related risk factors are the presence of chronic lung diseases, like Chronic Obstructive Pulmonary Disease (COPD) and asthma, as well as smoking history and the patient's overall state of health. Age and obesity are relatively minor factors; and the precise risks associated with malnutrition and recent viral infections are unknown.

TABLE 27.2: Risk factors for postoperative pulmonary complications*

Patient-Related Risk Factors	*Procedure-Related Risk Factors*
Age >60 years	Surgical site
Smoking	Type of anesthesia
General state of health (ASA class >2)	Duration of surgery (>3 hours)
Nutritional status	Type of incision
Obesity	Emergency/elective surgery
COPD/Asthma/OSA	Immobilization
Abnormal chest radiograph	Inadequate pain control
Antecedent respiratory tract infection	

*Modified from reference 20

1. *Smoking*: Smoking is a risk factor for postoperative pulmonary complications, as has been demonstrated repeatedly since the first report in 1944.[23] Smoking increases risk even among those without chronic lung disease.[24] The available data are mixed, but suggest a modest increase in risk for postoperative pulmonary complications among current smokers, and when the patient is older or has smoked longer. The ill effects of smoking are mainly related to the high level of carboxyhemoglobin in smokers, which usually ranges from 3% to 15%. Carboxyhemoglobin reduces the amount of hemoglobin available to bind with oxygen and shift the oxygen-hemoglobin saturation curve to the left, which facilitates the loading of oxygen onto hemoglobin, but impairs unloading at the tissues. Nicotine can cause systemic vasoconstriction and increase both the heart rate and the systemic blood pressure. A statistically significant reduction in complications occurs only when patients discontinue smoking for at least eight weeks prior to the surgery.[25]
2. *Chronic lung disease*: Among studies reporting multivariable analyses, chronic obstructive pulmonary disease is the most commonly identified risk factor for postoperative pulmonary complications. While one may consider patients with restrictive lung diseases with severe limitations to have an increased risk for postoperative pulmonary complications, the literature did not support an estimate of the magnitude of this risk in this group.[21]

   Chronic obstructive pulmonary disease: COPD is the single most important patient-related risk factor for the development of postoperative pulmonary complications. The relative risk of pulmonary complications attributable to COPD is three to four folds.[22] Physicians should aggressively treat patients with COPD who, before surgery, do not have optimal reduction of symptoms and airflow obstruction on physical examination and who do not have optimal exercise capacity. Elective surgery should be deferred if acute exacerbation is present. The treatment and preparation of patients who have COPD before elective surgery are the same as those in nonoperative settings.

   The increased incidence of postoperative pulmonary complications in patients with COPD is due, in part, to an increase in the CC, favoring the development of the areas of low ventilation-to-perfusion ratios and atelectasis. In addition, in patients who continue to smoke, impaired ciliary function and chronic tracheobronchitis may be contributing factors. Although not precisely quantified in the literature, the risk for postoperative respiratory complications appears to increase significantly (greater than 50%) when the FEV_1 is below 65% of predicted. The risk is also increased in patients who are hypercapnic. However, patients with an FEV_1 as low as 450 ml have tolerated surgery safely. Therefore, the potential benefits of the operative procedure must be weighed against the operative risk in every individual patient.

   Asthma: Patients with acute bronchospasm are probably at increased risk for perioperative complications, since several maneuvers associated with anesthesia may aggravate bronchospasm.[26] However, the same is not true for patients with stable asthma.[21,22] Before surgery, patients should be free of wheezing, with a peak flow greater than 80% of the predicted or personal best value. If necessary, the patient should receive oral corticosteroids to achieve this goal. A short course of perioperative corticosteroids does not increase the incidence of infection.

   Obstructive sleep apnea (OSA): OSA increases the risk for airway management difficulties in the immediate postoperative period. In one case-control study, nonsignificant trends were seen toward the higher rates of reintubation, hypercapnia and hypoxemia for patients with OSA.[27] Pulmonary hypertension is particularly associated with a significant perioperative risk. As cardiovascular dysfunction in OSA patients can be modified by treatment, it is important to identify patients not known to have OSA and have them treated to improve their perioperative outcomes, as well as to improve their general health.

   Restrictive lung diseases: While some experience has been reported with patients undergoing thoracic and corrective orthopedic surgery, very little data exist with regard to abdominal and extremity surgery. Postoperative respiratory complications after corrective surgery in patients with kyphoscoliosis, have been reported in up to 20% of these patients, with pleural space-related processes (e.g. pneumothorax, pleural effusion, bronchopleural fistula and empyema) among the most common. Video-Assisted Thoracoscopic (VAT) approaches have emerged as good alternatives to open thoracotomy in such patients.
3. *Age*: Previous reviews have suggested that age is not a predictor of postoperative pulmonary complications and they are more strongly related to coexisting conditions than to chronologic age.[22] However, a recent review found that the risk of pulmonary complications increases with the advancing age.[21]

These findings appear to hold true when lung tissue is resected. There have been many reports detailing the outcomes of lung resection in the elderly. The general concerns raised by the literature are that the operative mortality is greater in the elderly, operative risks for pneumonectomy are relatively high, and complications may be increased. Despite the study trends, the sum of the evidence suggests that surgery should not be withheld on the basis of age alone.[28]

4. *General health status:* Several integrated measures of comorbidity have been evaluated as the potential predictors of postoperative pulmonary complications. The widely used American Society of Anesthesiologists (ASA) classification, which was developed to evaluate the risk of overall perioperative mortality, is strongly predictive of postoperative pulmonary complications.[29] In addition, the Goldman cardiac-risk index, which includes factors from the patient's history, the physical examination, and laboratory data, also predicts pulmonary complications.[30]
5. *Obesity*: Despite the changes that occur in pulmonary mechanics and pulmonary functions in obese individuals, studies evaluating clinically meaningful pulmonary complications after surgery have generally found no increased risk attributable to obesity, even for patients with morbid obesity. Obesity is, however, clearly a risk factor for obstructive sleep apnea syndrome, which may be unmasked or exacerbated because of the use of postoperative analgesics or narcotics.[21]
6. *Others*: The risk of postoperative pulmonary complications in patients with viral upper respiratory infections is unknown. It is reasonable to delay truly elective surgery in patients with upper respiratory infection. Although patients with compromised nutritional status are at higher risk for developing postoperative pulmonary complications, aggressive preoperative nutritional support has not been shown to decrease postsurgical pulmonary morbidity.

Procedure-Related Risk Factors

Procedure-related risk factors are as important as patient-related factors in estimating risk for postoperative pulmonary complications. The surgical site is the most important predictor of pulmonary risk. Risk increases as the incision approaches the diaphragm; therefore, upper abdominal and thoracic surgery carries the greatest risk of postoperative pulmonary complications. Studies using multivariable analyses have found that prolonged surgery duration, ranging from three to four hours, is an independent predictor of postoperative pulmonary complications. The contribution of risk from the type of anesthesia itself has been controversial. Many have reported a lower risk of pulmonary complications among patients receiving spinal or epidural anesthesia than among those receiving general anesthesia, but the results have been inconsistent and the effect small.

Except for the reduced risk of postoperative thromboembolism, there is no clear evidence in the current literature that regional anesthesia results in better intraoperative or postoperative pulmonary function.[31,32] Emergency surgery has been identified as a significant predictor of postoperative pulmonary complications. Abdominal laparoscopic procedures and thoracoscopic lung resection are associated with less postoperative respiratory problems, as compared to open procedures because of reduced patient discomfort, shortened length of hospitalization and faster patient return to full activity. Prolonged bed rest and inactivity following surgery is a major risk factor for deep venous thrombosis and pulmonary embolism.

PREOPERATIVE EVALUATION

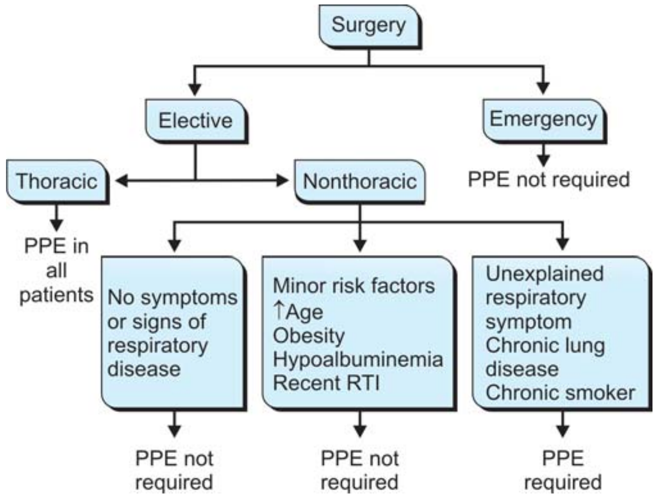
This section of the chapter is intended to provide an evidence-based approach to the preoperative physiologic assessment of a patient undergoing either thoracic or nonthoracic surgery. After discussing the initial evaluation, which is to be done in all the patients, the pulmonary specific evaluation is discussed. The task of the preoperative physiologic assessment is to identify patients who are at increased risk for both perioperative complications and long-term disability from surgical resection of lung tissue using the least invasive tests possible.

A. Initial Evaluation

Initial preoperative pulmonary evaluation is required in almost all elective surgeries. In case of emergency, the surgery should not be delayed for the cause of pulmonary evaluation unless the likelihood of perioperative mortality or postoperative complication is so high that the surgery should not be performed (Fig. 27.1). The principal components of preoperative evaluation of the surgical patient are: (1) the history and physical examination, (2) the chest radiograph, (3) spirometry, and (4) arterial blood-gas analysis.

History and Physical Examination

A careful history taking and physical examination are the most important parts of preoperative pulmonary risk



PPE: Preoperative pulmonary evaluation; RTI: Respiratory tract infection

Fig. 27.1: Suggested approach for preoperative evaluation (See text for details)

assessment. One should seek a history of respiratory symptoms (like chronic cough, dyspnea and chest pain) including symptoms of sleep apnea. History should also include the patient's functional capacity and the degree of the limitation of activity. Smoking history should be taken in detail and all patients should be encouraged to quit smoking. If there is history of recent respiratory tract infection, it is advisable to delay the surgery till it gets cured.

The physical examination may identify the findings suggestive of unrecognized pulmonary disease. Among such findings, decreased breath sounds, dullness to percussion, wheezes, rhonchi, and a prolonged expiratory phase predict an increase in the risk of pulmonary complications. It should include an evaluation for signs of metastatic spread (e.g. lymph node enlargement, hepatomegaly or focal neurologic deficits) and the presence of cardiac failure and pulmonary hypertension.

Chest Radiograph

The current evidence suggests that this test only rarely provides unexpected information that influences preoperative management and clinicians may predict most abnormal preoperative chest radiographs by history and physical examination. Thus, a preoperative chest radiograph is indicated when there are new or unexplained symptoms or signs, when there is a history of underlying lung disease and no recent chest radiograph, or when thoracic surgery is planned.

Spirometry

Spirometry is a simple, inexpensive, standardized, and readily available test, which is used to diagnose the obstructive and restrictive lung diseases. But it does not translate into effective risk prediction for individual patients. There is a consensus that all candidates for lung resection and coronary artery bypass should undergo preoperative spirometry; its value before extrathoracic surgery, however, remains unproven. Moreover, the data do not suggest a prohibitive spirometric threshold below which the risks of surgery are unacceptable. So, preoperative spirometry is reserved for patients undergoing thoracic surgery, or patients having unexplained chest symptoms especially those suggestive of COPD, or history of cigarette smoking.

Arterial Blood Gas (ABG) Analysis

A partial pressure of arterial carbon dioxide ($PaCO_2$) greater than 45 mm Hg is identified as a strong risk factor for pulmonary complications, based on several case series, as it usually indicates chronic respiratory failure.[33,34] Hypercapnia has been a relative contraindication to lung resection.[35] So, it is recommended that the arterial blood gas analysis should be done in the patients of chronic lung disease, or who have a significant pulmonary process and patients undergoing lung resection. The routine use of ABG is not recommended in all patients.

B. Pulmonary-Specific Evaluation

Pulmonary-specific evaluation is required in all patients undergoing lung resection surgeries. The two main aims of pulmonary specific evaluation are to assess the perioperative mortality and morbidity to tolerate the surgical procedure; and, to assess the postoperative pulmonary function to allow reasonable quality of life. A number of physiologic tests exist for this purpose, although, there is no single test that is a "gold standard" in accurately predicting complications. This part of preoperative evaluation is divided into the three stages of tests, which are performed in a sequential manner, that help to risk-stratify the patients prior to the planned surgery.

Stage I

The first stage consists of tests to assess the overall functions of both the lungs.

1. *Spirometry:* Of all the indices assessed by spirometry, FEV_1 is regarded as being the best for predicting the

complications of lung resection in the initial assessment, and it is the one most commonly used for decision making. The FEV_1 helps to predict those at risk for postoperative complications, including death. Little evidence exists to utilize one cutoff absolute value of FEV_1 to permit resection of varying extent. Preoperative values of 2 L for pneumonectomy and 1.5 L for lobectomy have been suggested. The risk of postoperative respiratory complications also increases significantly when the FVC or Maximal Voluntary Ventilation (MVV) is less than 50% predicted.

2. *Diffusion capacity*: Diffusing capacity of the lung for carbon monoxide (DL_{CO}) reflects alveolar membrane integrity and pulmonary capillary blood flow in the patient's lungs. A retrospective study found DL_{CO} as most important predictor of mortality and was the sole predictor of postoperative pulmonary complications.[36] Absolute cut-offs are not clearly established in the literature. However, individuals with a preoperative DL_{CO} less than 60% predicted were found to have more frequent respiratory complications, hospitalizations for respiratory compromise, and worse median dyspnea scores than individuals with preoperative DL_{CO} more than 60% predicted.[37] Predicted Postoperative (PPO) DL_{CO} has been found to be an independent predictor of pulmonary complications, morbidity, and death in other studies.[38,39] A combined value, the Predicted Postoperative Product (PPP), was found to be the best predictor of surgical mortality in one study. The PPP is the product of the PPO FEV_1 and PPO DL_{CO}. A PPP greater than 1650 was found in 75% of those who died and 11% of those who survived surgery.[40]

Stage II

The next stage consists of tests that measure differential lung function and estimate the PPO lung function. There are three techniques to predict the postoperative values—segment method, radionuclide scanning technique and quantitative computed tomography.

1. *Segment method*: The simplest methods to predict postoperative pulmonary function involve calculating the portion of all bronchopulmonary segments that will remain after resection. The postoperative lung function should be approximated by the preoperative value multiplied by this portion. The conventional method is to use 19 total segments as the starting value (10 on the right and 9 on the left).

$$\text{PPO } FEV_1 = \text{Preoperative } FEV_1 \times (1 - x/19)$$

where x is the number of lung segments to be removed.

The other method is to use the number of subsegments, corrected for those that were obstructed preoperatively. A regression equation relating the predicted and measured lung function was developed from this method (measured = 0.85 predicted + 0.286 +/– 0.296, r = 0.821).[41] A predicted postoperative FEV_1 of 800 ml has been used as a cutoff for withholding resectional lung surgery, based on the clinical impression that below 800 ml many patients are disabled and develop carbon dioxide retention.

2. *Quantitative ventilation-perfusion scan*: Ventilation lung scans (using inhaled ^{133}Xe) and perfusion lung scans (using ^{99}Tc macroaggregates) are equally accurate in calculating the PPO FEV_1, although perfusion scanning is more commonly used because it is technically easier to perform. The general principle of this technique is same as for the segment methods.

$$\text{PPO } FEV_1 \text{ postlobectomy} = \text{Preoperative } FEV_1 \times (1 - y/z)$$

where y is the number of functional or unobstructed lung segments to be removed, and z is the total number of functional segments.[17]

$$\text{PPO } FEV_1 \text{ postpneumonectomy} = \text{Preoperative } FEV_1 \times (\text{\% of function of affected lung})$$

Normally, the right lung contributes 55% of lung function, while the left lung contributes 45% of lung function. The PPO and %PPO DL_{CO} after lung resection can be calculated using the same formula. Using this method, the r-value for correlation between predicted and actual postoperative FEV_1 has been as high as 0.88.[42,43] That for DL_{CO} has been as low as 0.68.[43] The anatomic method can also be applied to segmentectomies because lobectomy does not cause a significantly greater loss of function when compared to segmentectomy.[17]

3. *Quantitative computed tomography*: In this technique, the volume of lung with attenuation between –500 and –910 Hounsfield units is used to estimate functional lung volume. By calculating the lung volume in the area to be resected as a portion of total lung volume and using the principles stated above, the predicted postoperative pulmonary function may be estimated. However, this technique is not widely used despite the evidence of it being better than radionuclide quantitative perfusion imaging.[44]

The PPO FEV_1 can also be calculated without performing a split lung function test. According to Juhl and Frost formula,[45,46]

$$\text{PPO FEV}_1 = \text{Preoperative FEV}_1 \times \{1 - (S \times 5.26)/100\}$$

where S is the number of bronchopulmonary segments involved.

Other tests assessing differential lung function include bronchospirometry (the measurement of oxygen uptake in each lung, individually), lateral position testing, and total unilateral pulmonary artery occlusion. These tests are no longer performed in the preoperative evaluation as they are invasive; require specialized equipment, a high level of technical expertise and concerns over the reproducibility of results.[35]

Stage III

The third stage comprises of exercise testing that provide the confirmatory evidence of operability.

Exercise testing: Exercise testing has been used to determine whether individuals with unacceptable lung function by other measures might be able to tolerate resection. Formal testing such as symptom-limited cycle ergometry and simpler tests, including exercise oximetry, stair climbing and shuttle walking, have been studied. Cycle ergometry with incremental workloads, which measures VO_2, VO_2 max, minute ventilation, and carbon dioxide output with concomitant monitoring of ECG, BP, oximetry, while the patient exercises to the maximal end point or to the symptom-limited maximum, is probably the best form of exercise testing.

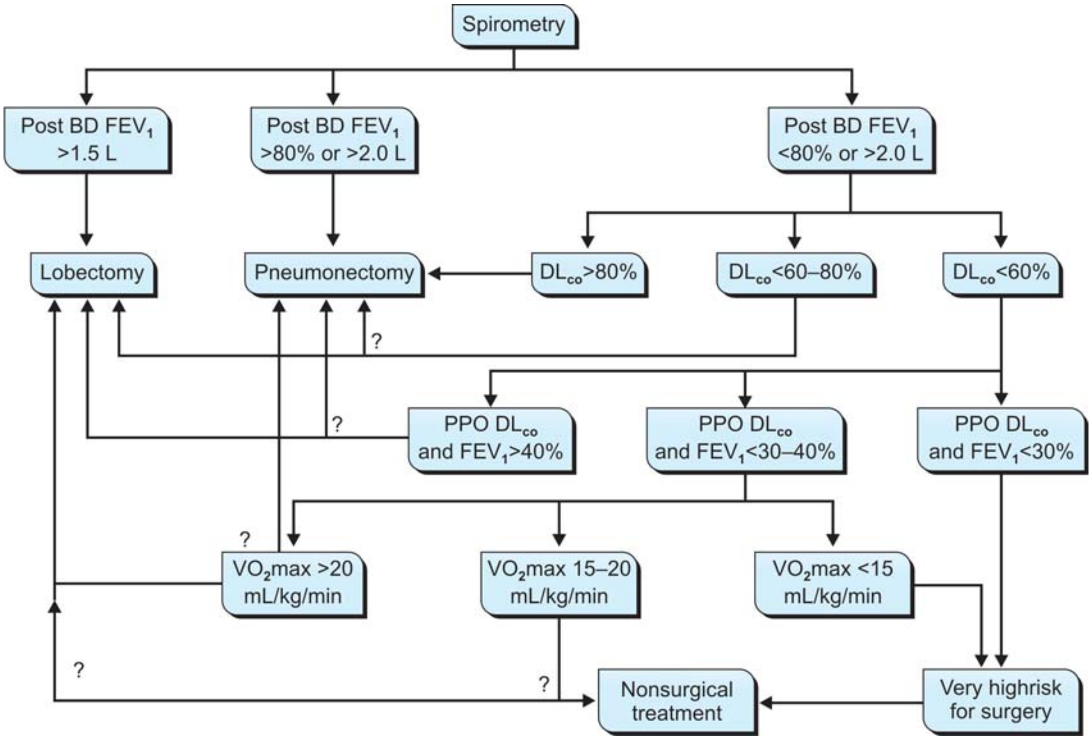
Exercise testing could be fixed exercise challenge, in which a sustained level of work is performed; and incremental exercise testing, in which the work rate is sequentially increased to a desired end point. Exercise capacity, measured as the VO_2 max during Cardiopulmonary Exercise Testing (CPET), has been shown to be a predictor of postoperative complications, including postoperative and long-term mortality.[47-54] A VO_2 max less than 15 to 20 ml/kg/min is associated with an increased incidence of postoperative complications.

Other simpler tests can be used in situations where a complete CPET is not possible. In one study, a 4% or greater desaturation during exercise oximetry performed better than FEV_1 and DL_{CO} in predicting postoperative pulmonary complications, including death and respiratory failure.[55] Stair-climbing test and six-minute walk tests are other technologically simpler tests that have been used to estimate the risk from lung resection. The significant risk of postoperative pulmonary complications has been demonstrated in patients who are unable to climb two flights (where one flight is the equivalent of 12 steps). Patients who are unable to complete a six-minute walk of more than 500 feet are unacceptable candidates for lung resection. The distance obtained during a shuttle walk test, a type of incremental exercise test, where an individual walks back and forth over a defined distance at an incremental and progressive rate has correlated well with VO_2 max obtained on a treadmill. Walking 25 shuttles (10 m each) approximated a VO_2 max of 10 mL/kg/min.[56]

RECOMMENDED APPROACH

Preoperative pulmonary evaluation for lung resection should be done by a multidisciplinary team. And no patient should be denied surgery on the basis of age alone. Operability for pneumonectomy is determined in the event that this procedure should become necessary, either to remove the tumor completely or because of an intraoperative complication. Patients with post-bronchodilator FEV_1 (PostBD FEV_1) more than 2 L (or more than 80% predicted normal) and more than 1.5 L are suitable for pneumonectomy and lobectomy respectively without further evaluation, unless there is the evidence of interstitial lung disease or undue dyspnea on exertion. In that case the DL_{CO} should be measured. DL_{CO} should also be measured, if the preoperative FEV_1 is less than these values. The patient is cleared for pneumonectomy and lobectomy, if the DL_{CO} is more than 80% and 60 to 80% predicted normal respectively.

If an individual is not clearly operable after initial testing (DL_{CO} less than 60% predicted normal), then PPO lung function should be estimated. If the PPO FEV_1 and PPO DL_{CO} is less than 30% predicted normal or the product of the PPO FEV_1 and PPO DL_{CO} is less than 1650, then there is a very high risk of perioperative death and cardiopulmonary complications. In such cases, surgery should be avoided. The patient can undergo lobectomy and possibly pneumonectomy, if the PPO FEV_1 and PPO DL_{CO} is more than 40% predicted. The patient is considered borderline, if this number is between 30% and 40% of the predicted value. In borderline patient, if confirmatory evidence of operability is required, an exercise test should be performed. If the VO_2 max is less than 15 mL/kg/min with both PPO FEV_1 and PPO DL_{CO} less than 40% predicted, then the individual is at very high risk for perioperative death and cardiopulmonary complications. The patient is cleared for lobectomy and possibly pneumonectomy if the VO_2 max is more than 20 mL/kg/min. The borderline patients are at high risk for surgery and it is recommended that these patients be counseled about nonoperative treatment options for their disease (Fig. 27.2). Individuals with very poor lung



Spirometry
Post BD FEV₁ >1.5 L
Post BD FEV₁ >80% or >2.0 L
Post BD FEV₁ <80% or >2.0 L
Lobectomy
Pneumonectomy
DLco>80%
DLco<60–80%
DLco<60%
?
PPO DLco and FEV₁>40%
PPO DLco and FEV₁<30–40%
PPO DLco and FEV₁<30%
VO₂max >20 mL/kg/min
VO₂max 15–20 mL/kg/min
VO₂max <15 mL/kg/min
Nonsurgical treatment
Very highrisk for surgery

function may be considered for combined Lung Volume Reduction Surgery (LVRS) and lung cancer resection, if the emphysema is heterogeneous and involves primarily the lobe to be resected, provided both the FEV_1 and the DL_{CO} are more than 20% predicted.[17,28,57]

OPTIMIZING THE CHANCE OF A SUCCESSFUL OUTCOME

Preoperative and intraoperative strategies to reduce the risk of pulmonary complications follow logically from the established risk factors. There has been little rigorous research on how one might increase the chance of a successful outcome in the lung resection candidate. Areas that have been considered include smoking cessation, pulmonary rehabilitation, and the immediate postoperative care regimen includes the use of bronchodilators, corticosteroids and antibiotics (Table 27.3).

Current and former smoking has been shown to be a risk factor for postoperative pulmonary complications, and an optimal period of abstinence prior to surgery is

TABLE 27.3: Risk reduction strategies*

Preoperative

Smoking cessation (ideally, a minimum of 8 weeks prior to surgery)
Optimize treatment of COPD/asthma/OSA
Antibiotics for respiratory tract infection
Pulmonary rehabilitation
Weight reduction for severely obese individuals
Lung expansion maneuvers

Intraoperative

Limit duration of surgery to <3 hours
Regional anesthesia
Minimal invasive or laparoscopic surgery

Postoperative

Early patient mobilization and ambulation
Lung expansion maneuvers (incentive spirometry, deep-breathing exercises)
Adequate analgesia (epidural/ intercostal nerve blocks)
Thromboprophylaxis

*Modified from reference 22

associated with fewer pulmonary complications, better wound healing, and shorter length of stay in the ICU.[58] Accordingly, the preoperative evaluation of smokers should include enrolling them in smoking cessation programs or, at a minimum, provide a time when a serious discussion can occur regarding smoking. At least 12 to 24 hours of preoperative abstinence should be sought to achieve possible cardiovascular benefits and optimally six to eight weeks of preoperative abstinence to decrease the incidence of postoperative respiratory complications. Pulmonary rehabilitation programs have been shown to improve outcomes and decrease the postoperative pulmonary complications in different studies, whether used before or after the surgery.[59,60] There is no direct evidence to support an additional role for bronchodilators and antibiotics in the lung resection candidate beyond what would be considered the standard use for COPD or asthma.

Intraoperative strategies involve collaboration with anesthesia and surgery colleagues. These strategies include selecting a lower risk or briefer (less than 3 hours) procedure for high-risk patients with few opportunities for risk reduction, recommending laparoscopic rather than open surgeries when possible, using spinal or epidural anesthesia in the lieu of general anesthesia, and avoiding pancuronium.[20]

Lung-expansion maneuvers lower the risk of atelectasis by increasing lung volume. Deep breathing exercises, incentive spirometry and intermittent positive pressure breathing have been studied most extensively. However, there is no evidence to support a significant difference between any of the three modalities.[61] Preoperative education in lung expansion maneuvers reduces pulmonary complications to a greater degree than instruction that begins after surgery.[62] The advantage of postoperative Continuous Positive Airway Pressure (CPAP) and Bilevel Positive Airway Pressure (BiPAP) is that, it is not dependent on the patient's effort.[63] It is costly, however, and requires more intensive involvement by hospital personnel than other methods. Because less costly lung-expansion maneuvers are available, physicians should not use CPAP or BiPAP for the primary prevention of complications.

Conventionally, parenteral narcotics have been used for postoperative analgesia. However, concerns over adverse respiratory effects may lead to inadequate dosing and inadequate pain relief. Alternative approaches like patient-controlled analgesia, epidural analgesia and intercostals nerve blocks have been used to overcome this issue. These pain control strategies reduce splinting and promote the ability to take deep breaths after thoracic, aortic and upper abdominal surgeries. While pain control is improved when compared with systemic opioids, studies of their ability to reduce postoperative pulmonary complications have shown conflicting results.

Prophylaxis for thromboembolism constitutes a key management issue in all patients. Finally, careful monitoring for postoperative complications constitutes a key element in all surgical patients. Other perioperative interventions like total parenteral nutrition, pulmonary artery catheterization,[21] chest physiotherapy in the absence of excessive secretions or sputum production, and routine application of positive end-expiratory pressure in mechanically ventilated patients have been shown to be ineffective.

CONCLUSION

The goal of preoperative evaluation of the patient being considered for surgery is to identify everyone who has an acceptable chance of tolerating that procedure, while guiding those found to have the greatest likelihood of major complications about the options that exist. The evaluation of candidates for thoracic surgery differs substantially from the evaluation before general surgery. By using the above described tests and recommendations, the best option for cure to many patients can be provided.

Arterial Blood Gases and Acid Base Balance

Vinaya S Karkhanis, Jyotsna M Joshi

INTRODUCTION

Arterial Blood Gas (ABG) analysis is the sampling of blood from an artery for the determination of Oxygen (O_2), Carbon Dioxide (CO_2) and acid content. ABG represents the "ultimate" test[1] in clinical practice in the evaluation of severity and causes of:

- Lung gas exchange abnormalities using Arterial Oxygen Tension (PaO_2) and Arterial Carbon Dioxide Tension ($PaCO_2$)
- Acid-base disturbances using pH, $PaCO_2$ and Serum Bicarbonate (HCO_3).

PHYSIOLOGY OF GAS EXCHANGE

The primary function of the respiratory system is to provide oxygen to the cells at a rate adequate to satisfy their metabolic needs by the uptake of O_2 and discharge of CO_2. Inhaled oxygen enters the lungs and reaches the alveoli. Oxygen passes quickly through this air-blood barrier into the blood in the capillaries while carbon dioxide passes from the blood into the alveoli and is then exhaled (Fig. 28.1). Three processes essential for this exchange are ventilation, diffusion and perfusion. Abnormalities of any of these functions result in inadequate gas exchange indicated by low PaO_2 with or without elevated $PaCO_2$.[2,3]

Gas diffuses from alveoli to the blood in the pulmonary capillaries or vice versa across the thin alveolar-capillary membrane made up of the pulmonary epithelium, the capillary endothelium and their fused basement membranes. The diffusing capacity of the lung for a given gas is directly proportionate to the surface area of the alveolar-capillary membrane and inversely proportionate to its thickness.

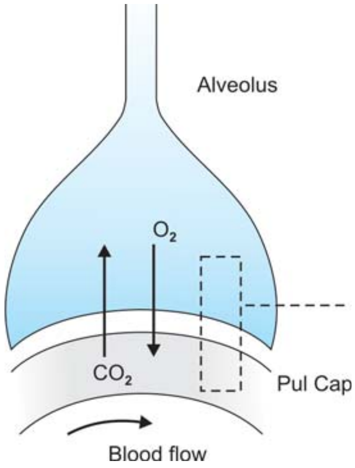

Fig. 28.1: Alveolar gas exchange unit

O_2 diffusion depends on the following:[4]

- Alveolar ventilation/capillary perfusion ratio, which establishes the partial pressure gradient of O_2 between alveolus and plasma
- Physical characteristics of the alveolar-capillary interface
- Capillary blood volume available for gas exchange
- Hemoglobin concentration
- Reaction rate between O_2 and hemoglobin.

Ventilation-Perfusion Relationship[5]

Ventilation and perfusion are normally matched in the lungs so that gas exchange (ventilation) nearly matches pulmonary arterial blood flow (perfusion). The concentration of Oxygen (PO_2) in any lung unit is measured by the relation of ventilation to blood flow and presented as Ventilation/Perfusion Ratio ($\dot{V}/\dot{Q}$). Ventilation-perfusion mismatch results in abnormal gas exchange. Shunt and dead space are terms used to describe extreme conditions where either blood flow or ventilation does not meet the other in the lung as it should for gas exchange to take place.

Diffusion and $\dot{V}/\dot{Q}$ abnormalities result in alveolar (A)-arterial (a) PO_2 difference. PAO_2 can be calculated using the equation:

$PAO_2 = FIO_2\ (Patm - PH_2O) - (PaCO_2/R)$

At sea level, $FIO_2 = .21$, $PH_2O = 47$, P breath = 760, $PaCO_2$ measured by lab analysis, R = 0.8

$PAO_2 = (150 - PaCO_2/0.8)$

$P\ (A\text{-}a)\ O_2 = (150 - PaCO_2/0.8) - PaO_2$

PaO_2 is measured by lab analysis.

Normal P (A-a) O_2 gradient = 10, increasing by 4–6 per decade over 50.

Alterations in Gas Exchange

The mechanisms of abnormal gas exchange and their characteristic features are as follows:

1. Reduced fraction of inspired O_2-Fi O_2 (e.g. high altitudes)
   - Low PaO_2 that improves by O_2 administration
   - PAO_2-PaO_2 is normal
   - $PaCO_2$ is normal.
2. Hypoventilation
   (Reduced ventilatory drive, e.g. obesity hypoventilation syndrome) or reduced effective alveolar ventilation, e.g. end stage lung disease)
   - Low PaO_2 that improves by O_2 administration
   - PAO_2-PaO_2 is normal in central hypoventilation and increased in alveolar hypoventilation
   - Increase in $PaCO_2$.
3. Diffusion defect [e.g. Interstitial Lung Diseases (ILDs)]
   - Low PaO_2 that improves by O_2 administration
   - PAO_2-PaO_2 increased
   - $PaCO_2$ is normal.
4. Ventilation-perfusion ($\dot{V}/\dot{Q}$) imbalance (e.g. emphysema)
   - Low PaO_2 that improves by O_2 administration
   - PAO_2-PaO_2 is increased
   - $PaCO_2$ normal.
5. Shunt effect [e.g. Adult Respiratory Distress Syndrome (ARDS)]
   - Low PaO_2 that does not improve after O_2 administration (refractory hypoxaemia)
   - PAO_2-PaO_2 is increased
   - $PaCO_2$ is normal.

PHYSIOLOGY OF ACID BASE BALANCE

Acids and Bases

An acid is defined as any compound, which forms hydrogen ions in solution. For this reason, acids are sometimes referred to as "proton donors." A base is a compound that combines with hydrogen ions in solution. Therefore, bases can be referred to as "proton acceptors." Both acids and bases are related to the concentration of hydrogen ions present. Acids increase the concentration of hydrogen ions, while bases decrease the concentration of hydrogen ions. The acidity or basicity of something therefore, can be measured by its hydrogen ion concentration. In 1909, the Danish biochemist SP Sorensen[6] invented the pH scale for measuring acidity. The body's balance between acidity and alkalinity is referred to as acid-base balance and is indicated on the pH scale.

pH

The pH, which is an abbreviation for "pouvoir hydrogene" or "power of hydrogen," is a measuring unit of acidity and alkalinity of a solution. The pH is calculated by the Sorensen formula as the negative logarithm of the hydrogen ion concentration, i.e.

$pH = -\log10[H^+]$ where $[H^+]$ is the hydrogen ion concentration.

At rest, the normal blood pH of a human being is slightly alkaline, with a pH around 7.4 (7.35–7.45) on the pH scale. Anything above that value is considered alkaline; anything below is described as acidic. Both, in their extremes (below 6.8 or above 7.8) are not compatible with life.

The Henderson-Hasselbalch equation[7] describes the correlation of metabolic and respiratory regulations, which maintain pH.

$pH = 6.1 = \log HCO_3/0.3 \times PaCO_2 = pK+$ kidney/lung where, pK is the negative logarithm of the dissociation constant.

Kassirer and Bliech[8] have rearranged the Henderson equation that relates H^+ (instead of pH) to PCO_2 and HCO_3 and have derived an expression, which has great clinical utility.

$H^+ = 24 \times PCO_2 / HCO_3$ nmol/L

Where, 24 = the numerical value of the solubility coefficient of carbon dioxide and the dissociation constant of carbonic acid.

$PaCO_2$ = arterial blood partial pressure in mm Hg

HCO_3^- = arterial blood bicarbonate concentration in mmol/L

H^+ = arterial blood H^+ ion concentration in nmol/L

Normally, $H^+ = 24 \times 40/24 = 40$ nmol/L which is equivalent to normal pH of 7.4.

The Hydrogen Ion

The hydrogen ion consists of a single positively charged particle (the proton). The metabolic processes within the body add a daily load of H^+ ions to the body. Small amounts are formed from the oxidation of amino acids and the anaerobic metabolism of glucose to lactic and pyruvic acid. For more, acid is produced as a result of CO_2 release from oxidative (aerobic) metabolism. Although, CO_2 does not contain hydrogen ions, it rapidly reacts with water to form carbonic acid (H_2CO_3), which further dissociates into hydrogen and bicarbonate ions (HCO_3-). This reaction is shown below:

$$CO_2 + H_2O <=H_2CO_3 => HCO_3- + H^+$$

This reaction occurs throughout the body and in certain circumstances is speeded up by the enzyme carbonic anhydrase.

Acid Base Balance

As already discussed, acid base balance is indicated by pH, which alters with change in H^+ ion concentration in the body. The hydrogen ion is highly reactive and will combine with bases or negatively charged ions at very low concentrations. These H^+ ions if not properly deal with; the body would produce a disastrous rise in H^+ ion concentration and a catastrophic fall in the pH. Proteins contain many negatively charged and basic groups within their structure. Thus, a change in pH will alter the ionization of a protein, which may in turn affect its functioning. At more extreme hydrogen ion concentrations, a protein's structure may be completely disrupted (the protein is then said to be denatured). Although, most enzymes function optimally around physiological pH, any disturbances in pH may result in abnormal respiratory and cardiac function, derangements in blood clotting and drug metabolism. The body thus, needs to maintain the pH within a normal range in spite of variation in dietary intake of acid and alkali and endogenous acid production. Three systems are involved for this maintenance: Blood and tissue buffering, excretion of CO_2 by the lungs, and the renal regulation of excretion and regeneration of HCO_3 with excretion of H^+.

TABLE 28.1: Buffer mechanisms for acid base balance

Buffers	*Mechanism*	*Time*
Extracellular fluid	Bicarbonates	Immediate
Intracellular fluid	Phosphates, HCO_3^-	2-4 hours
Lungs	Increased rate of breathing to decrease CO_2	Minutes to hours
Kidneys	H^+ ion excretion and HCO_3^- reabsorption and generation	Hours to days

Buffers[9] *(Table 28.1)*

Buffers are substances, which react with an acid or base and thereby, minimize changes in pH. In the body fluids, there are several buffer systems. In blood, main buffers are the hemoglobin, bicarbonate system and plasma proteins. Within the cells, the buffers include bicarbonates, phosphates and proteins. The bicarbonate buffer system is of primary importance in regulating acid base balance.

Bicarbonates (Fig. 28.2A): The bicarbonate carbonic acid reaction is important in regulating acid base balance. It constitutes a weak buffer system, which can be used as a measure of all acid base reactions in the body. Its efficiency is improved since CO_2 is removed by the lungs and HCO_3^- regenerated by the kidney.

The CO_2 produced by tissue metabolism diffuses into plasma and red blood cells. The enzyme carbonic anhydrase within the red blood cells catalyses the formation of carbonic acid.

$$H_2O + CO_2 = H_2CO_3-$$

The carbonic acid within the red blood cells is dissociated as:

$$H_2CO_3 <=> H^+ + HCO_3-$$

The bicarbonate within red blood cells diffuses out into the plasma, while the H^+ ions are mopped up by the hemoglobin. The loss of HCO_3^- ion from the cell is compensated by the entry of an chloride ions from the plasma. When the blood reaches the lungs, the chloride ion shift is reversed and bicarbonate ions enter the red blood cells in capillary. The bicarbonate within red blood cells breaks down into water and CO_2.

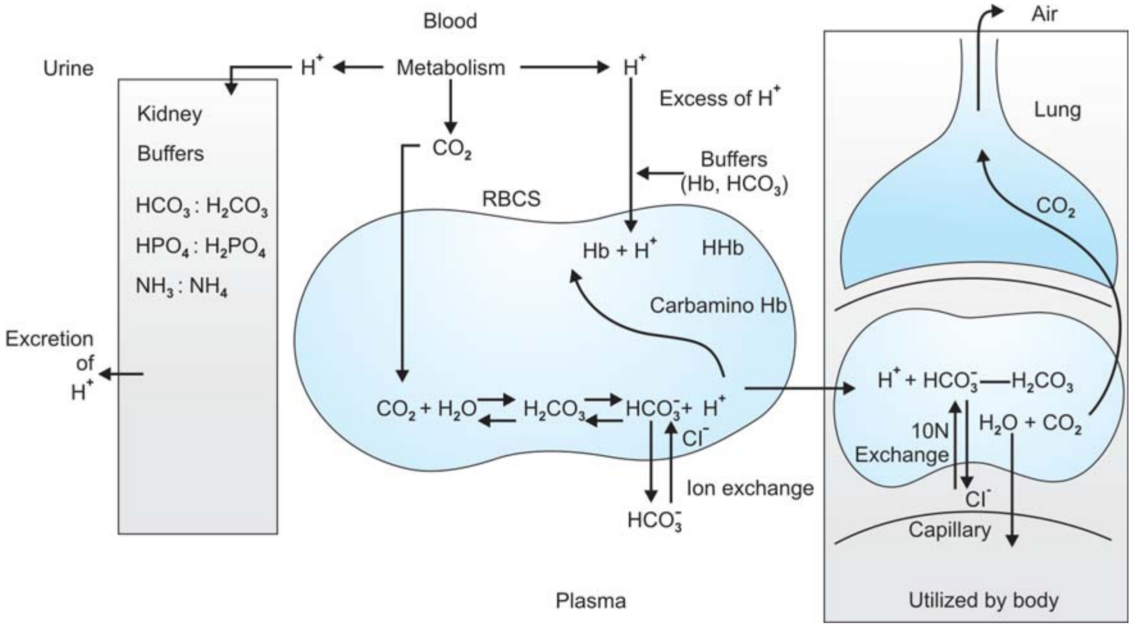

Fig. 28.2A: Acid base balance: Blood and tissue buffering and CO_2 elimination

In acid base balance the bicarbonate carbonic acid reaction is as follows when, H$^+$ enters tissue fluids:

$$H^+ + HCO_3\text{-} \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O$$

Hemoglobin (Fig. 28.2A): The hemoglobin buffer is an important one, as it is involved in handling the largest daily acid load of the body. It is not only important in the carriage of oxygen to the tissues, but also in the transport of CO_2 and in buffering hydrogen ions. Hemoglobin binds both with CO_2 and H$^+$ and acts as a powerful buffer. Deoxygenated hemoglobin has the strongest affinity for both CO_2 and H$^+$; thus, its buffering effect is strongest in the tissues. Little CO_2 is produced in red cells, which either combines directly with hemoglobin reversibly to form carbaminohemoglobin or combines with water to form carbonic acid. In the lungs the CO_2 is released and passes down its concentration gradient into the alveoli.

Proteins: Other buffers, such as plasma proteins, phosphates and histidine act in a similar way to bicarbonates; however, these are present in smaller concentrations in intracellular and extracellular fluid. Many proteins notably albumin, contain weak acidic and basic groups within their structure. Therefore, plasma and other proteins form important buffering systems. Intracellular proteins limit pH changes within cells, whilst the protein matrix of bone can buffer large amounts of hydrogen ions in patients with chronic acidosis.

Respiratory Regulation (Fig. 28.2A)

It is clear when considering the Henderson equation that variations in PCO_2 alter the pH. The effect is rapid and influences both the intracellular fluid and extracellular fluid. Arterial PCO_2 varies inversely with alveolar ventilation and directly with carbon dioxide production. By excreting volatile acids, lung regulates $PaCO_2$. Normally, CO_2 production and excretion are balanced, which maintains CO_2 at 40 mm Hg. When rate of CO_2 production increases, it stimulates $PaCO_2$ sensitive chemoreceptors at central medulla with resultant rise in the rate and depth of breathing. This hyperventilation will maintain $PaCO_2$ at normal range. Respiratory regulation acts rapidly and has double buffering power as compared to chemical buffers.

Renal Regulation[10]

Maintenance of pH of the blood within its normal range is done by the renal regulation of excretion of H$^+$ ions with urine buffers and also by retaining and excreting HCO_3^- ions depending on the utilization of HCO_3- during the titration process of buffering in extracellular fluid. As the blood pH decreases, the kidneys will compensate by retaining HCO_3- and as the pH rises, the kidneys excrete HCO_3- through the urine. Although, the kidneys provide an excellent means of regulating acid-base balance, the system may take from hours to days to correct the imbalance. The kidney generates bicarbonate

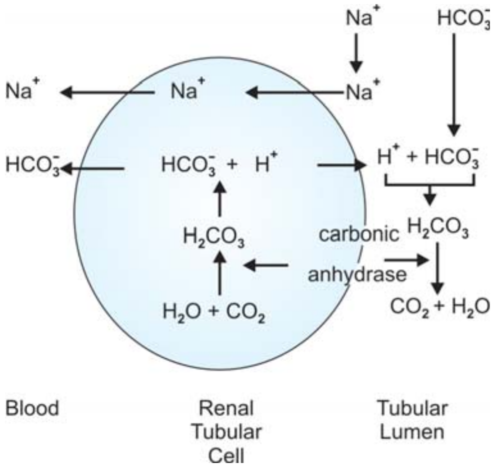

Fig. 28.2B: Acid base balance: Regulation of excretion and reabsorption of HCO_3^- by kidneys

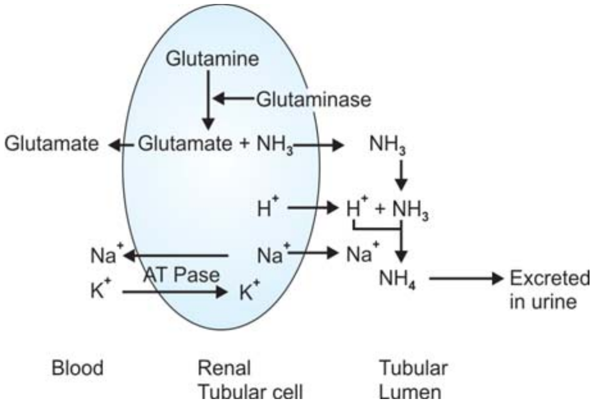

Fig. 28.2C: Acid base balance: Regulation of excretion of H^+ ions with formation of NH_4

through nonbicarbonate buffer systems, such as phosphates and proteins and by metabolizing glutamine. The renal handling of electrolytes also influences acid base balance.

Regulating Excretion and Reabsorption of Bicarbonates (Fig. 28.2B)

Bicarbonate is filtered by the glomerulus. The quantity of bicarbonate in the filtrate is dependent on the plasma bicarbonate and the glomerular filtration rate. Reabsorption of bicarbonate happens in the proximal renal tubules at a rate which is dependent on the PCO_2. The higher the PCO_2, the greater the degree of bicarbonate reabsorption; the lower the PCO_2, the lesser the degree of reabsorption of bicarbonate and the greater its excretion. This enables respiratory acidosis to be compensated through the retention of bicarbonate (metabolic alkalosis), and respiratory alkalosis to be compensated by an increased excretion of bicarbonate (metabolic acidosis). This can be explained as follows:

Filtered HCO_3- combines with secreted H^+ ions to form carbonic acid, which dissociates to form CO_2 and H_2O in the renal tubules. This CO_2 crosses into the tubular cell and combines with H_2O to form carbonic acid, which dissociates to form HCO_3- and H^+ ions. Bicarbonates passes back into the blood and H^+ back into the tubular fluid in exchange for sodium.

Regulating excretion of hydrogen ion: Hydrogen ions are actively secreted in the proximal and distal tubules by the means of various buffers such as phosphates and ammonia. Kidneys by using phosphate buffers (HPO_4-) remove H^+ ions while conserve bicarbonates. Hydrogen ions are secreted in exchange for sodium ions. Under the influence of carbonic anhydrase in tubular cells,

$$H^+ + HCO_3\text{-} = H_2CO_3$$
$$H_2CO_3 \rightarrow HCO_3\text{-} + H^+$$

Bicarbonate ions are reabsorbed. The H^+ ion excreted into the tubular infiltrate is mopped up by a buffer, which is excreted via the urine.

Formation of ammonia (Fig. 28.2C): The major site for ammonia (NH_3) production is in the proximal convoluted tubule epithelium although it can be formed in tubular epithelia throughout the nephron.[13] Ammonia is formed in the tubular cells by the conversion of glutamine to glutamate. The NH_3 diffuses into the renal tubular lumen where it binds H^+ ion to form a nondiffusible ammonium ion (NH_4^+), which is subsequently excreted.[14] Ammonia combines with chloride and excreted via the urine, the reaction being controlled by the enzyme glutaminase. Excretion of ammonia allows the excretion of a significantly large quantity of H^+ ions via the kidney.

Reabsorption of sodium (Fig. 28.2D): The active reabsorption of sodium from the filtrate into tubule cells causes a potential gradient across the cell membrane. The positively charged H^+ion within the tubule cells thus passes across the membrane into the filtrate, and is buffered within the filtrate by a phosphate buffer.

$$H^+ + NaHPO_4 \rightarrow NaH_2PO_4$$

Sodium reabsorption and hydrogen ion excretion are interlinked. Sodium reabsorption is controlled by the action of aldosterone on ion exchange proteins in the distal tubule. These ion exchange proteins exchange sodium for hydrogen or potassium ions.

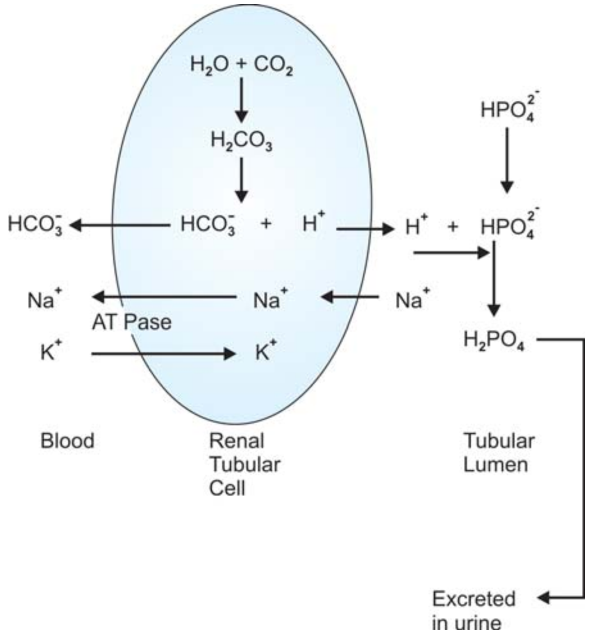

Fig. 28.2D: Acid base balance: Regulation of excretion of H^+ with phosphate buffers and electrolytes

Alterations in Hydrogen Ion Homeostasis

Disturbance of the body's acid-base balance results in the plasma containing either too many hydrogen ions (acidemia) or too few hydrogen ions (alkalemia). In other words, the pH is too low in acidemia (less than 7.35) whilst in alkalemia the pH is too high (more than 7.45). These disturbances may be due to respiratory causes (i.e. changes in $PaCO_2$) or non-respiratory or metabolic causes (i.e. changes in HCO_3^-). When the cause of the acid base disturbance has been discovered, the words acidosis or alkalosis may be used in conjunction with the physiological cause of the disturbance (i.e. respiratory acidosis, metabolic alkalosis, etc.).

ARTERIAL BLOOD GAS ANALYSIS

Applications

Blood gas analysis is indicated in any situation where assessment of arterial blood and tissue oxygenation, alveolar ventilation, gas exchange across the lungs or acid base status is required, for example:

- To document respiratory failure and to assess its severity
- To monitor patients on ventilators and to assist in weaning
- To assess acid base imbalance in cases with critical illness
- To assist in the diagnosis of conditions, e.g. ILD by exercise desaturation and increase alveolar arterial gradient and Obesity Hypoventilation Syndrome (OHS) by daytime hypercapnia
- To assess response to therapeutic intervention like supplemental oxygen administration and mechanical ventilation
- As a preoperative assessment in high-risk patients who require general anesthesia for major surgery.

Arterial Blood Sampling[11,12]

Arterial blood collection is the preanalytical stage, the stage where the greatest variance is likely to occur. It is critical to understand and control these variances. Examples of potential areas for error include the type of syringe, anticoagulant, storage. Blood for arterial blood gas analysis is drawn by direct arterial puncture. When frequent monitoring of ABG is required blood sample may also be obtained via an indwelling arterial cannula. The commonest artery used is the radial followed by the dorsalis pedis; rarely the brachial and the femoral vessels. With the change of ventilatory parameters or the FiO_2 at least five minutes (at least 30 minutes in cases of obstructive lung disease) should be allowed to obtain a steady state.

Checking Patency of Radial Artery

If the radial artery is to be used, the collaterality of blood flow to the hand must be checked by the Allen's test. Allen's test was devised for confirming the presence of radial arterial occlusion. First, the suspected radial artery is occluded at the wrist for three minutes and the hand color is compared with that of the other hand. If there is no change in color, the hand has sufficient collateral circulation through the ulnar artery. The ulnar artery is occluded next for three minutes. A positive Allen's test indicated by change in the color of the hand denotes the presence of radial artery occlusion and contraindicates radial artery puncture.

Drawing an Arterial Blood Sample

Direct arterial puncture is usually done with a 21 gauge or smaller needle. The wrist is kept immobilized and if necessary extended with a support just below the dorsum of the wrist. Under aseptic precautions and with (out) local anesthesia, the heparinized syringe with needle is introduced at an angle of 45° to the horizontal (Fig. 28.3). Heparin salt is the only anticoagulant acceptable for the measurement as it has little effect on the analytes measured.

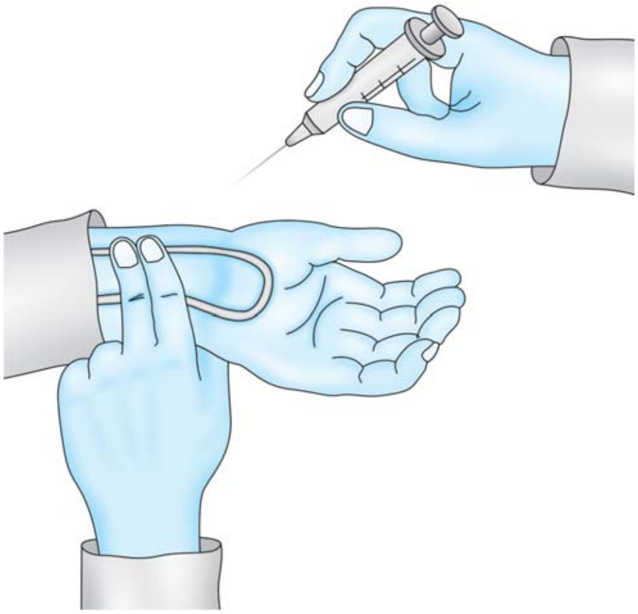

Fig. 28.3: Arterial puncture technique

The blood can then be aspirated in two ways. One is to penetrate the needle till it hits the bone and then withdrawing the needle while maintaining suction in the syringe till one sees bright red blood coming freely into the syringe. The other way is to penetrate the tissues while maintaining suction so that the artery is not pierced through and through. Traditionally, the blood volumes required are 2.7 to 3.0 mL. After drawing a sample, firm pressure must be applied at the site of arterial puncture for at least two minutes.

Transporting the Blood Sample for Analysis

It is acceptable to leave a sample at room temperature if the analysis will occur in 10 to 15 minutes. Blood is living tissue in which oxygen continues to be consumed and carbon dioxide continues to be produced, even after the blood is drawn into a syringe. Very high leukocyte values, as seen in leukemia patients, can cause a significant drop in the PO_2 over a short period. Hence, arterial blood samples must be placed in ice slurry or analyzed immediately. Elevated potassium levels have been observed in healthy individuals, even when the specimen was iced only for a few minutes. When potassium is measured, the specimen should be analyzed in 10 to 15 minutes and not iced. The following should also be considered in specimen preservation and transport:

- Removal of air contamination
- Capping the specimen

Failure to process sample properly is a common source of preanalytic error.

Arterial Blood Gas Equipment

The modern day equipment is a three-electrode system blood gas analyzer that measures three fundamental variables—PaO_2, $PaCO_2$ and pH. All other parameters, such as plasma HCO_3 are computed by software using standard formulae.

Using Venous Blood Gas (VBG) instead of ABG[13]

Various studies suggest that a venous sample is relatively accurate for acid-base assessment. The most obvious advantage to obtaining a VBG instead of an ABG is decreased pain for the patient. Also, a VBG sample can be drawn using the same Intravenous (IV) line that is used to draw blood for other lab tests, thus, necessitating only one puncture. This translates into decreased costs, labor and risk of needle stick injury to the health care provider. Furthermore, complications such as arterial laceration, hematoma and thrombosis rarely occur with venous blood sampling. Therefore, venous blood sample and venous blood gas analysis for pH, bicarbonate and PCO_2 is acceptable as a substitute for ABG analysis (Table 28.2). A venous sample may collected in a heparinized syringe and transported in the same way as an arterial sample for assessing the acid base status in the initial evaluation of patients particularly those presenting to the emergency department.

Serum Electrolyte Measurement

An electrolyte abnormality is often the first laboratory sign of an acid-base disorder. In any patient with a blood gas or acid-base abnormality serum electrolytes sodium, chloride and bicarbonate should always be measured by drawing a separate sample routinely. Since potassium is often deranged in acid-base disorders, hence it should also be measure additionally.

TABLE 28.2: Comparison of Arterial Blood Analysis (ABG) and Venous Blood Gas (VBG) values in healthy volunteers

	Arterial	*Venous*
pH	7.38–7.42	7.35–7.38
PCO_2	38–42 mm Hg	44–48 mm Hg
PO_2	90–100 mm Hg	40 mm Hg
HCO_3	24 mmols/L	21–22 mmols/L

Fig. 28.4: A typical automated ABG report

ARTERIAL BLOOD GAS INTERPRETATION

A typical ABG report is shown in the (Fig. 28.4). Despite several parameters available in the ABG report, the following are sufficient for interpretation:

pH: Arterial blood pH, normal 7.35–7.45

P_aCO_2 (PCO_2): Arterial CO_2 pressure, mm Hg, normal 35–45 mm Hg

P_aO_2 (PO_2): Arterial O_2 pressure, mm Hg, normal 95–100 mm Hg

HCO_3^-: Serum bicarbonate concentration, mEq/liter, normal 22–26 mmols/L

These parameters are written as:

7.40/40/98/24
PH/$PaCO_2$/PaO_2/HCO_3

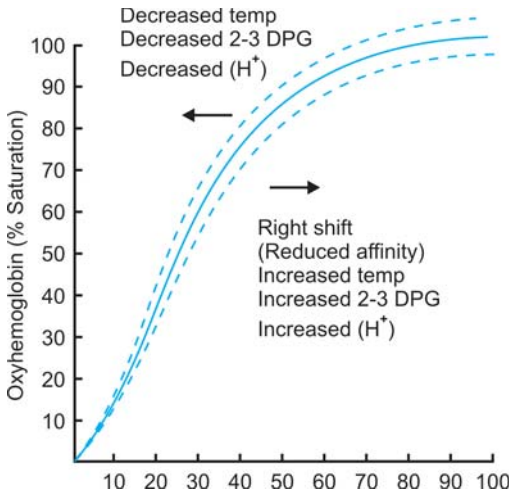

Fig. 28.5: Oxyhemoglobin dissociation curve

Using the above parameters ABG is analyzed for:

- Gas exchange
- Acid base status.

Gas Exchange

Oxygenation

Oxygenation is measured by the partial pressure of oxygen in arterial blood, P_aO_2 mm Hg, often written more simply as PO_2. Normal value of PO_2 is 95–100 mm Hg. Reduced PaO_2 indicates hypoxia/hypoxemia. Hypoxia refers to reduced oxygen pressure in the alveolus, while hypoxemia refers to low arterial oxygen pressure.

Oxygen saturation SaO_2/SpO_2: The basis for using O_2 saturation (SO_2) is the relationship of SO_2 to PaO_2 shown by the O_2 dissociation curve (Fig. 28.5). This curve shows that maximum saturation, greater than 90% is achieved at PaO_2 of 60 mm Hg, beyond, which increases in O_2 saturation is marginal. Thus, if the measured SO_2 is 90% the PaO_2 can be assumed to be 60 mm Hg.

Pulse oximetry[14]: Monitoring of O_2 saturation with Small Portable Pulse Oximeters (SpO_2) is a simple and effective way of monitoring O_2. Pulse oximetry using pulse oximeters measures the oxygen saturation of the blood. Oxygen saturation is calculated by shining light through tissue and measuring the light absorption on the other side of the tissue at two specific wavelengths. The site most commonly used is the fingertip, although the earlobe is also used. The light source consists of two light emitting diodes that emit light at known wavelengths, generally 660 nm and 940 nm. These wavelengths are used because oxyhemoglobin and reduced hemoglobin have different absorption spectra at these particular wavelengths.

Abnormal Gas Exchange

Hypoxemia: The partial pressure of O_2 in the arterial blood in normal individuals is 80 mm Hg or greater. When the value of O_2 on Arterial Blood Gas (ABG) analysis is less than 80 mm Hg the term hypoxemia is used (hypoxia is the term for reduced O_2 in the tissues). The following can serve as useful guidelines for assessing the degree of hypoxia:

- Mild hypoxemia: PaO_2 of 60–80 mm Hg. At this level, arterial blood is 90% saturated
- Moderate hypoxemia: PaO_2^- of 40–60 mm Hg. These values will be reflected in clinical signs, including tachycardia, hypertension and perhaps the appearance of cool extremities
- Severe hypoxemia: PaO_2 lower than 40 mm Hg. At these level serious arrhythmias, brain damage or death may ensue.

Alveolar-arterial oxygen gradient: Calculation of alveolar arterial O_2 gradient P (A-a) O_2, the difference between alveolar O_2 (PAO_2) and arterial O_2 (PaO_2), in presence of hypoxemia is useful in determining the cause of hypoxemia. The formula for alveolar O_2 (PAO_2) is 150-Pa CO_2/RQ, where, Respiratory Quotient (RQ) is .8 when breathing room air and 1 when on 100% O_2. The alveolar arterial gradient is normally up to 21 in young adults and subsequently increases by four to six for every decade of life. Increase P (A-a) O_2 indicates lung parenchymal disease.

Exercise hypoxemia: Exercise consists of a six-minute walk at a moderate pace on a flat surface performed under the supervision of a respiratory therapist. Patients are encouraged to walk at their own pace for six minutes, alternatively until target heart rate (200-age in years) is reached or until limited by shortness of breath or fatigue. Clinically significant desaturation is considered to be any SO_2 decrease of 4% or more to a nadir of 88% or less during exercise regardless of the baseline SO_2. Exercise hypoxemia/desaturation using a finger pulse oximeter -SpO_2 is a practical alternative to using ABG-SO_2. Demonstration of exercise hypoxemia/desaturation is useful for the diagnosis of ILD and other disorders and for prescribing oxygen therapy.

Oxygenation index: The P/F ratio, i.e. ratio of partial pressure of alveolar O_2 and fraction of inspired O_2 (PaO_2/FiO_2) is called the oxygenation index, an index on greater than 300 is considered normal. It is used to determine a diagnosis of ARDS. In the absence of cardiac or other major system involvement, an index less than 300 indicates, Acute Lung Injury (ALI) and an index of less than 200 indicates ARDS. Recently the S/F ratios, i.e. ratio of O_2 saturation (SO_2) and FiO_2 have been found to correlate with P/F ratios.[15] Since, SO_2 can be measured noninvasively with portable pulse oximeters use of S/F ratio to measure oxygenation is a simple and easy alternate to performing ABG. S/F ratios 315 and 235 correlate with P/F ratio of 300 and 200 for ALI and ARDS.

Hypercapnea: $PaCO_2$ is directly proportional to CO_2 production and indirectly proportional to alveolar ventilation, i.e. $PaCO_2$ = CO_2 production/alveolar ventilation. Increase in $PaCO_2$ level in blood is due to hypoventilation, which is due to central nervous system depression, neuromuscular or chest wall diseases, upper airway obstruction and due advanced lung diseases with reduced effective alveolar ventilation. In the case of OHS demonstration of daytime hypercapnea helps to distinguish the disorder from, Obstructive Sleep Apnea (OSA) syndrome. Hypercapnea is measured by the pressure of carbon dioxide in arterial blood as $PaCO_2$ mm Hg, often written more simply as PCO_2. Normal $PaCO_2$ is 35–45 mm Hg. An algorithm for the interpretation of O_2 and CO_2 (gas exchange) is shown in Flow chart 28.1.

Acid Base Status

Acidemia and alkalemia refer to alterations in the blood pH. Both respiratory and metabolic disorders can contribute to alterations in pH and are referred to as a respiratory acidosis or respiratory alkalosis and a metabolic acidosis or metabolic alkalosis. A single disorder may account for the observed acidemia or alkalemia, but often more than one disorder occurs concurrently. These are referred as mixed or complex acid base disorders. Acid base balance is assessed using the “three acid base variables”—pH, $PaCO_2$ and HCO_3 (Table 28.3).

While pH and $PaCO_2$ are directly measured during ABG analysis, HCO_3 levels are calculated using the Henderson-Hasselbalch equation. HCO_3 levels on serum chemistry are directly measured and are therefore more

TABLE 28.3: pH, PCO_2 and HCO_3 in primary acid base abnormality

Acidosis	*Alkalosis*
pH < 7.35	pH > 7.35
HCO_3 < 22 mmols/L (Metabolic)	HCO_3 > 26 mmols/L (Metabolic)
PCO_2 > 45 mm Hg (Respiratory)	PCO_2 < 35 mm Hg (Respiratory)

Flow chart 28.1: Algorithm for blood gas analysis: O_2 and CO_2

Consider V̇/Q̇ mismatch (With hypoventilation if PaCO₂ is high)

accurate. Therefore, routine serum electrolytes must always be performed to measure bicarbonate. Serum electrolytes also provide the levels of sodium and chloride, which are necessary for the calculation of anion gap.

Normal pH ranges from 7.35–7.45, less than 7.35 suggests acidosis and greater than 7.45 alkalosis. A disorder in which the primary abnormality is a change in the $PaCO_2$ is referred to as a respiratory disorder. Normal $PaCO_2$ ranges from 35–45 mm Hg. Reduced $PaCO_2$ less than 35 mm Hg is seen in respiratory alkalosis due to CO_2 washout related to hyperventilation. Elevated $PaCO_2$ greater than 45 mm Hg is seen in respiratory acidosis due to CO_2 retention associated with hypoventilation. A disorder in which the primary abnormality is a change in HCO_3 concentration in the blood is referred to as a metabolic disorder. Normal HCO_3 ranges from 22–26 mmols/L. Elevated HCO_3 greater than 26 mmols/L is seen in metabolic alkalosis and reduced HCO_3 less than 22 mmols/L is seen in metabolic acidosis. Thus, there are four types of acid base abnormalities respiratory alkalosis and acidosis and metabolic alkalosis and acidosis.

Metabolic acidosis can be clinically classified as:

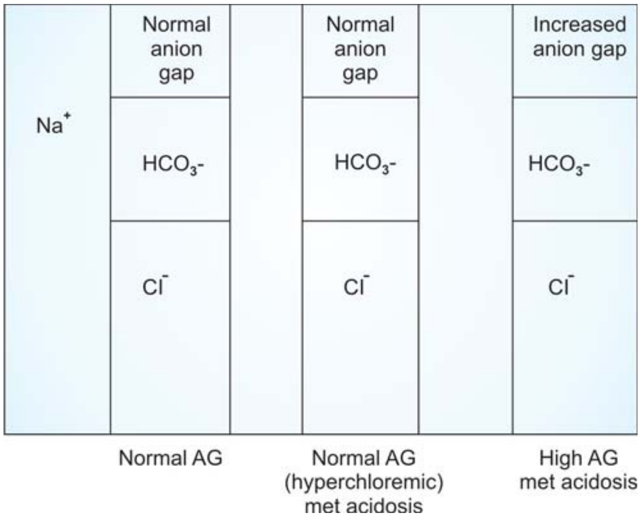
- Metabolic acidosis with normal anion gap
- Metabolic acidosis with increased anion gap.

Anion Gap (AG) [16,17] (Fig. 28.6)

The term anion gap represents the concentration of all the unmeasured anions in the plasma. The AG calculation is the sum of routinely measured cations minus routinely measured anions: $(Na^+ + K^+) - (Cl^- + HCO_3^-)$. However, because K^+ is a small value numerically, it is usually omitted from the AG equation. Thus, the anion gap is calculated by subtracting the serum concentrations of chloride and bicarbonate (anions) from the concentrations of sodium. The normal anion gap is 12 + 2 (mean + SD) mmols per liter.

$$\text{Anion gap (AG)} = (Na)-(Cl+HCO_3) = 12$$

Metabolic acidosis with normal AG occurs due to the loss of HCO_3, compensated by increase in chlorides. Increase in AG occurs due to the decreased excretion of fixed acids, addition of lactate or ketones or ingestion of certain toxins.



Na⁺

Normal AG (hyperchloremic) met acidosis
High AG met acidosis

Fig. 28.6: Figure shows normal, metabolic acidosis with normal anionic gap due to increase in Cl^- and increased anion gap metabolic acidosis where no Cl^- compensation occurs. Excess anion gap (AG) = total AG – normal AG =12 mmols/L, and AG– 12 + HCO_3 = 22–26 mmols/L.

Types of Primary Acid Base Abnormality[18]

Primary Acid Base Disorders (Flow chart 28.2)

Primary acid-base disturbances are defined as metabolic or respiratory based on clinical context and whether the primary change in pH is due to an alteration in serum HCO_3 or in PCO_2. If the pH is lower than 7.35, then lowered bicarbonate (metabolic acidosis) or elevated PCO_2 (respiratory acidosis) would be primary abnormalities. If the pH is higher than 7.45, then elevated bicarbonate (metabolic alkalosis) or a lowered PCO_2 (respiratory alkalosis) would be primary.

Metabolic Acidosis
Mixed
Respiratory Acidosis
Metabolic Alkalosis
Mixed
Respiratory Alkalosis

Metabolic alkalosis: pH > 7.45, $PaCO_2$ 35–45 mm Hg, serum HCO_3 >26 mmols/L

Volume contraction (vomiting, over diuresis, ascites), hypokalemia, alkali ingestion (bicarbonate), excess corticoids.

Metabolic acidosis: pH < 7.35, $PaCO_2$ 35–45 mm Hg, serum HCO_3 < 22 mmols/L

High Anionic Gap Metabolic Acidosis (HAGMA)

$$(Na)\text{-} (Cl+HCO_3) > 12$$

Uremia, ketoacidosis, lactic acidosis, ethyl/methyl alcohol poisoning.

Normal Anionic Gap Metabolic Acidosis (NAGMA) or hyperchloremic metabolic acidosis.

$$(Na)\text{-} (Cl+HCO_3) = 12$$

Diarrhea, Renal Tubular Acidosis (RTA), carbonic anhydrase inhibitor

Respiratory alkalosis pH > 7.45, PCO_2 < 35 mm Hg, serum HCO_3 <=24 mmols/L

Hyperventilation due to anxiety, pregnancy, drugs (salicylates, progesterone), ILDs, catastrophic CNS event

Respiratory acidosis pH < 7.35, PCO_2 > 45 mm Hg, serum HCO_3 22–26 mmols/L

Central nervous system depression, pleural disease, lung disease, musculoskeletal disorders.

Compensated Acid Base Disorders (Table 28.4)

When an acidosis or alkalosis develops acutely pH changes occur, thus, showing uncompensated disorder. If the disturbance persists for some time compensatory buffering mechanisms help restore the pH to normal values. However, in this process significant changes in $PaCO_2$ and HCO_3 occur opposite to the primary abnormality. As a result of the compensatory mechanism the pH approaches, but does not completely return to normal. This principle allows us to use the direction of pH change to identify the primary disorder even when compensation is present. The pH, PCO_2, and bicarbonate values could be the same in two patients with different abnormalities. Clinical correlation would readily differentiate between the two. As is the case for other diagnostic tests, acid-base abnormalities must not be interpreted without clinical correlation.

Mixed Acid Base Disorder

Mixed acid-base disorders can be identified by determining the expected compensatory response to a given change in the primary abnormality and assuming that any value that falls outside this range represents an

TABLE 28.4: Formulae for compensation in acid base disturbances

Disorder	*Primary changes*	*Response and limits*	*Expected compensation*
Metabolic Acidosis	↓HCO_3	↓PCO_2 (PCO_2 usually 10)	$PCO_3 = (HCO_3 \times 1.5) + 8 \pm 2$ pH = 7. (15 + HCO_3) (12)
Metabolic Alkalosis	↑HCO_3	↓PCO_2 (PCO_2 usually <55)	$PCO_2 = (HCO_3 \times 0.9) + 8 \pm 2$ pH = 7. (15 + HCO_3)
Respiratory Acidosis	↑PCO_2	↑HCO_3 (HCO_3 < 30[acute]) (HCO_3 < 45[chronic])	For every 10 mmols ↑ in PCO_2 HCO_3 ↑ by 2 in acute and by 3-4 in chronic disorder
Respiratory Alkalosis	↓PCO_2	↓HCO_3 (HCO_3 < 18) [acute]) (HCO_3 < 12 [chronic])	For every 10 mmols ↓ in PCO_2 HCO_3 ↓ by 2 in acute and by 5 in chronic disorder

*If values more than expected for compensatory mechanism consider mixed acid base disorder.

additional primary disorder. A maximum of three disorders can be present at a given time, as respiratory alkalosis caused by hyperventilation and respiratory acidosis caused by hypoventilation cannot occur simultaneously. Mathematical equations[19] (Fig. 28.3) and nomograms[20] are available for identifying mixed disorders. Unfortunately, mathematical equations, different for acute and chronic disorders, can be difficult to memorize and nomograms, though simple to use do not help understand the physiology behind the abnormality detected.[21] Additionally nomograms may not be readily available to the clinician. A simpler alternative, which will identify most clinically important disorders, is to calculate the delta gap.

Delta Gap[22]

The coexistence of two metabolic acid-base disorders may be apparent by calculating the delta gap. The difference between the patient's anion gap and the normal anion gap is termed the delta gap or the delta-delta. For every unit rise in the anion gap, the HCO_3 should lower by one (by buffering). Thus, if the delta gap is added to the measured HCO_3, the result should be in the normal range for HCO_3, i.e. 22–26 mmols/L. Elevation greater than 26 mmols/L indicates the additional presence of a metabolic alkalosis and reduction less than 22 mmols/L indicates additional non AG metabolic acidosis. Thus,

$$\text{Delta gap} = \text{anion gap} - 12$$
$$\text{and, delta gap} + HCO_3 = 22\text{–}26 \text{ mmols/L}$$

The physiologic principle behind this is i) that the body does not generate a large anion gap as a compensatory mechanism even for a chronic alkalosis. Therefore, a substantial increase in unmeasured anions indicates a primary disorder, a metabolic acidosis, regardless of the pH or the bicarbonate concentration and ii) each mmol decrease in bicarbonate is accompanied by a mmol increase in the anion gap, the sum of the new (excess) anion gap and the remaining (measured) bicarbonate value should be equal to a normal bicarbonate concentration.

INTERPRETATION OF ARTERIAL BLOOD GAS

Use the following six easy steps to interpret an ABG report.[23,24] However, the "golden rule" of ABG interpretation is: "Always look at the patient first."

1. Look at the PaO_2 (<80 mm Hg) and O_2 saturation (<90%) for hypoxemia
2. Look at the pH (7.35–7.45): Low acidosis, high alkalosis
3. Look at the $PaCO_2$ (<35 mm Hg- > 45 mm Hg) and HCO_3 (<22 mmols/L ->26 mmols/L)
   HCO_3 is abnormal and the abnormality *(acidosis / alkalosis)* matches pH it is primary metabolic abnormality
   CO_2 is abnormal and the abnormality *(acidosis / alkalosis)* matches pH it is primary respiratory abnormality
4. Are the CO_2 or HCO_3 of opposite type? If so, there is compensation
5. Is there an anion gap? (Na - Cl - bicarbonate > 12). If no, analysis is done
6. If yes, AG metabolic acidosis is present.
   Next, calculate delta (Δ) gap, i.e. (anion gap – 12)
   Add measured bicarbonate to the delta gap
   (Measured AG – 12) + HCO_3

If it is greater than 26, there is a metabolic alkalosis as well.

If it is less than 22, there is a non-anion gap metabolic acidosis, too.

PITFALLS IN ARTERIAL BLOOD GAS INTERPRETATION

The following are common errors in performing and interpreting ABG:

- Not drawing the electrolytes and ABG at the same time
- Using the HCO_3 on the ABG, which is a calculated value (must use the HCO_3 from electrolytes)
- Failing to make sure the ABG correlates with patients clinical situation.

EXAMPLES

ABG Report 1

Diagnosis: 33 years old man with diabetic ketoacidosis

ABG = 7.0/14/90/4

Electrolytes: Na = 128, Cl = 90, HCO_3 = 4, Glucose = 800

Interpretation:
O_2= normal
pH(7.0) = acidosis
PCO_2(14)= alkalosis
HCO_3 (4) = acidosis .... primary abnormality, type metabolic

Compensation: PCO_2 is opposite (alkalotic)
Anion Gap (128 – 90 + 4= 34) = AG acidosis
Δ gap= AG –12= 34 – 12 = 22+HCO_3 (+ 4) = 26, no additional metabolic problem

Final interpretation: AG metabolic acidosis with compensatory respiratory alkalosis, compensation is partial.

ABG Report 2

Diagnosis: 23 years old man with asthma on high dose steroid therapy
ABG = 7.48/44/75/32

Electrolytes: Na = 134, Cl = 90, HCO_3 =32

Interpretation:
O_2: Normal
pH (7.48) = alkalotic
PCO_2 (44) = normal
HCO_3 (32) = alkalosis .... primary abnormality, type metabolic

Compensation: None
AG (134) – (90+32) = 12 =normal

Final interpretation: Metabolic alkalosis

ABG Report 3

Diagnosis: 50 years old woman with interstitial lung disease
ABG = 7.46/24/55/16

Electrolytes: Na = 130, Cl = 106, HCO_3 =15

Interpretation:
O_2: Hypoxemia
pH (7.46) = alkalosis
PCO_2 (24) = alkalosis .... primary abnormality, type (chronic) respiratory
HCO_3 (16) = acidosis

Compensation: HCO_3 (acidotic) opposite
AG (136) – (110+15)= 11 normal
Final Interpretation: Respiratory alkalosis with compensatory metabolic acidosis, complete compensation.

ABG Report 4

Diagnosis: 60 years old man with chronic obstructive pulmonary disease
ABG = 7.36/54/55/28

Electrolytes: Na = 140, Cl = 100, HCO_3 =28

Interpretation:
O_2: Hypoxemia
pH (7.36) = Normal
PCO_2 (54) = acidosis ...... primary abnormality, type (chronic) respiratory
HCO_3 (28) = alkalosis

Compensation: Metabolic HCO_3 alkalotic
AG (140 – 100 +28) = 12, normal

Final interpretation: Respiratory acidosis with compensatory metabolic alkalosis, complete compensation.

Nuclear Imaging in Pulmonary Medicine

BR Mittal, Sunil HV

INTRODUCTION

Nuclear medicine is an exciting frontier field of medical practice where the minute quantities of unsealed radioisotopes are used for understanding the human body, both in healthy, as well as the diseased individuals. The procedures, which employ open radionuclide sources have become an important tool in medical sciences for diagnosis, therapy and clinical research. Most diagnostic radionuclides emit gamma rays while radionuclides emitting beta particles are used in therapeutic applications. Radiopharmaceuticals after administration to the patient emit gamma rays that are detected externally by sophisticated instruments such as the gamma camera or the Positron Emission Tomography (PET) scanners. This process is unlike a diagnostic X-ray where external radiation is passed through the body to form an image. Planar studies provide a two-dimensional image whereas tomography provides three-dimensional images. The two most widely used emission tomographic studies are Single Photon Emission Computed Tomography (SPECT) and PET. Nuclear Medicine also plays a pivotal role in the diagnosis and the management of various pulmonary disorders. The various nuclear medicine procedures in pulmonology include ventilation scan, perfusion scan and positron emission tomography. (This chapter is an outline of the current applications of nuclear medicine in the routine clinical practice. For more details, the reader may refer to specific nuclear medicine books or periodicals).

PULMONARY ANATOMY AND PHYSIOLOGY

A proper interpretation of Ventilation/Perfusion ($\dot{V}/\dot{Q}$) lung scans requires the proper understanding of the pulmonary vascular segmental anatomy and physiology. The respiratory system consists of airways and two lungs. The airways are divided 23 times from the trachea to the alveoli. The first 16 of these divisions up to the terminal bronchioles are involved in the transportation of gases. The remaining seven divisions, which include the respiratory bronchioles and alveoli, are involved in the gas exchange. There are approximately 350 million alveoli, each enmeshed by a capillary web, arising from precapillary arterioles having a diameter of 10–30 microns. The lower zones of lungs are better ventilated and perfused normally. However, the rate of increase in ventilation from the apex to the base is relatively less compared to the increase in the blood flow. In the recumbent position, this hydrostatic gradient decreases and is reoriented to an anteroposterior plane. Effect of posture on regional pulmonary blood flow in rats has also been demonstrated recently using Ga-68-microspheres PET.[1] Increased perfusion to the upper lobes in an upright patient is suggestive of Congestive Heart Failure (CHF), increased left atrial pressure or alpha-1-antitrypsin deficiency.

INVESTIGATIONS

Ventilation Imaging

Ventilation in an erect patient is greater at the lung base than at the apex. In supine position, there is relatively a uniform distribution of ventilation. Ventilation scan is primarily used in addition to perfusion scan and the chest X-ray for the diagnosis of pulmonary embolism. Only ventilation scan is used for studying the transfer of gases across the capillaries. Ventilation studies may be

TABLE 29.1: Characteristics of agents used for ventilation

Agent	*Category*	*Usual dose (MBq)*	*Gamma emission*	*Half life*	*Drawbacks*
Tc99m DTPA	Aerosol	20-30	140 keV	6 hours	Deposition in central airways
Technegas	Aerosol	20-30	140 keV	6 hours	Expensive, availability
Xe133	Gas	555-740	81 keV	5.24 days	Only posterior and single breath hold views are possible
Xe127	Gas	370-740	172, 203, 375 keV	36.4 days	Only posterior and single breath hold views are possible
Kr81m	Gas	40-400	190 keV	13 sec	Expensive

performed using any of the following agents[2-6] (Table 29.1):

Tc99m-DTPA Aerosols

The most commonly used ventilation agent in India is Tc99m-Diethylenetriaminepentaacetic Acid (Tc99m-DTPA) aerosol. Technetium that is produced from a Mo99-Tc99m generator system is the main workhorse in nuclear medicine. This decays with gamma energy of 140 keV and half life of six hours. About 25–30 mCi of Tc99m-DTPA is injected into a shielded aerosol system. Aerosols of Tc99m-DTPA are generated by running oxygen through the aerosol system at a rate of 8 liters/minute. Patient is made to breathe via a face mask for two to three minutes with his nose clipped. The expired air is captured in a disposable plastic bag to avoid contamination. Particles produced are generally of 0.5–0.8 microns in diameter, which are delivered to the alveoli like gases during inhalation. Particles larger than one micron deposit in the tracheobronchial tree due to inertial impaction and gravitational sedimentation. After sometime, aerosolized Tc99m-DTPA crosses the alveolar-capillary membrane and enters the bloodstream where it is filtered by the kidneys and excreted. In normal subjects, the pulmonary clearance of Tc99m-DTPA has a half-time of over 60 minutes (1–1.5 hours).[2] Unlike gases, multiple projections can be obtained due to the persistence of activity in the lungs. In patients with obstructive airway disease, excessive tracer in the proximal bronchial tree is often seen due to turbulent airflow. The critical organ is the urinary bladder. The usual radiation exposure to the lungs is about 100 rads.[2] A normal lung ventilation image performed with Tc99m-DTPA aerosols is shown in Figure 29.1.

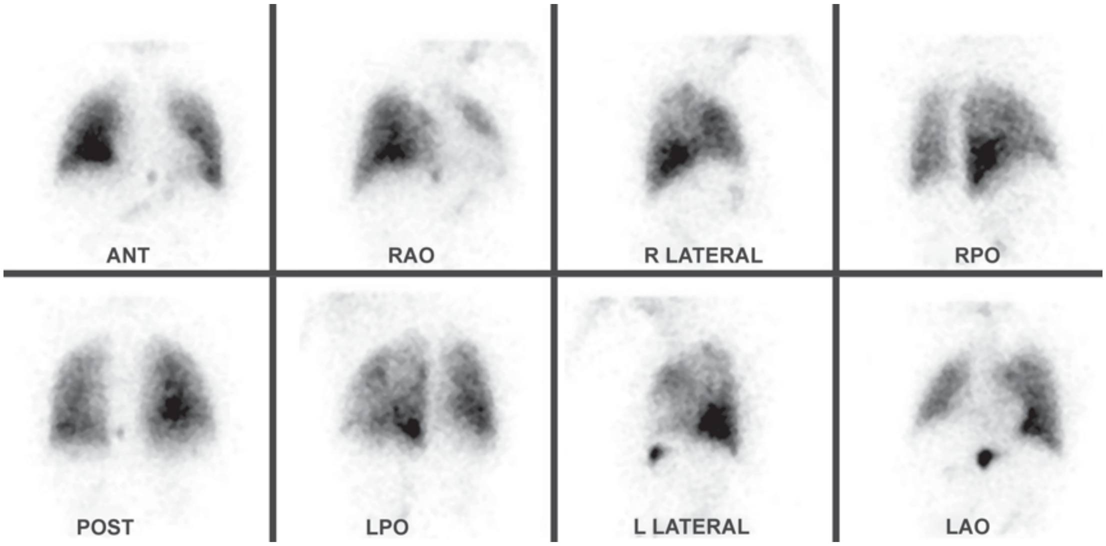

Fig. 29.1: Normal ventilation study of the lungs performed with Tc99m-DTPA aerosols. Uniform distribution of tracer activity is noted throughout both lungs

Tc-99m Technegas

Technegas and pertechnegas are being used in Australia and some centers in Europe. In this method, Tc99m gas is passed over heated carbon particles at a high temperature of 2000–2500°C in the presence of 100% argon gas. Fine particles of technegas are generated, which provide a uniform distribution over the entire lung field. This property of technegas is particularly useful in patients with COPD.

Xenon-133

It is a fission product of U-235 having a physical half-life of 5.24 days and a low energy gamma emission (81 keV).[3,4] The usual dose for inhalation is 15–25 mCi, but it can be administered intravenously in saline. It requires a separate exhaust ventilation system to avoid contamination of the laboratory. Often, only the posterior view is possible. Typical ventilation scan using Xe-133 consists of three phases:

i. *Single breath (wash in)*: The patient takes a single deep inspiration and holds it for as long as possible. This imparts information about regional ventilation and can detect 50 to 60% of ventilation defects associated with obstructive airway disease.
ii. *Equilibrium*: During this phase, the patient performs normal tidal respirations for three to five minutes while rebreathing a mixture of Xenon-133 and oxygen. In this view, overall lung volume is demonstrated as tracer equilibrates between all aerated portions of the lungs. It is the least sensitive to detect obstructive airway abnormalities. However, adequate duration of rebreathing ensures diagnostic quality washout phase.
iii. *Washout*: Inhalation of Xenon-133 is discontinued and the patient breaths room air or oxygen while exhaling the xenon into a charcoal trap. Normally, Xenon-133 clears from the lungs within two or three minutes. Retention of tracer activity beyond three minutes is noticed in obstructive airway disease. The washout phase of the exam can detect about 90% of abnormalities associated with obstructive airway disease. Xenon is overall more sensitive than aerosolized Tc99m-DTPA for detecting obstructive lung disease.

Xenon 127

Xe-127 has also been used for lung ventilation studies.[5] It is cyclotron produced radionuclide with a physical half-life of 36.4 days. It has three gamma emissions: 172 keV (25%), 203 keV (68%) and 375 keV (18%).

Krypton-81m

It is produced from a Rubidium-81/Krypton-81m generator system. Krypton-81m decays with a gamma emission of 190 keV and a physical half-life of only 13 seconds. This provides an exact comparison of ventilation and perfusion as the ventilation images can be acquired immediately after each perfusion view without moving the patient.[6]

Perfusion Imaging

Lung perfusion scan is typically performed by injecting Tc99m-Macroaggregated Albumin (Tc99m-MAA) intravenously. The particle size is generally between 10–90 microns. These particles are trapped in the pulmonary precapillary arterioles. On an average, this dose contains 5,00,000 particles, which obstruct nearly 0.1% of the precapillary arterioles.[7] The number of particles need to reduce to about 1,00,000 in patients with pulmonary arterial hypertension (acute right heart failure may occur due to limited pulmonary vascular reserve) and in those with known right to left shunts (may produce symptoms due to lodging of particles in the cerebral/coronary circulations). In neonates, the number of particles should be reduced in the range of 10,000–50,000. The biological half-life of MAA in the lungs is about six to eight hours. The particles get degraded into smaller particles by enzymatic hydrolysis and are phagocytized by Reticuloendothelial (RE) cells.[2] Thus the occlusion of arterioles is only temporary. The critical organ, i.e. the lung receives a dose of about 1 radian (1 cGy) from a typical 5 mCi dose[2]. The kidneys and bladder receive moderate exposure largely from the excretion of degraded albumin. Figure 29.2 represents a normal lung perfusion images performed with Tc99m-MAA.

Ventilation/Perfusion ($\dot{V}/\dot{Q}$) Imaging

Acquisition and Interpretation

Imaging is performed using a large field of view camera coupled with a parallel hole, high-resolution collimator. The scan protocol includes multiple static images in eight standard views (anterior, posterior, right lateral, left lateral, right anterior oblique, left anterior oblique, right posterior oblique and left posterior oblique) with the patient lying in supine position. Each perfusion image is acquired for 5,00,000–7,50,000 counts. SPECT imaging is performed wherever deemed necessary. The ventilation images are acquired for 1,00,000 counts or five minutes. It may be performed before or after the perfusion study. In a normal scan, all the views show uniform tracer distribution without any defect. Sometimes, one sees a few artifacts on $\dot{V}/\dot{Q}$ images.

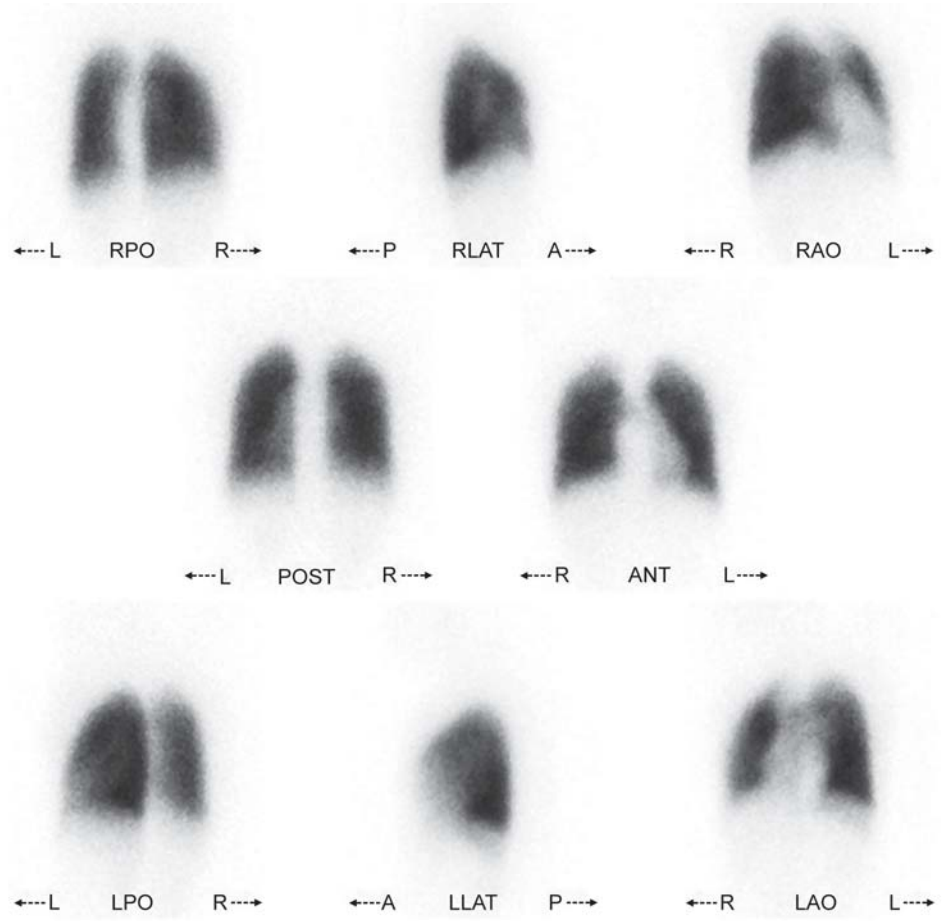

Fig. 29.2: Normal perfusion study of the lungs performed with Tc99m- macroaggregated albumin (Tc99m-MAA). Uniform distribution of tracer activity is noted throughout both lungs

i. *Artifacts on $\dot{V}/\dot{Q}$ images:*
   - Hot Spots, which occur due to the injection of blood clots inadvertently formed in the syringe. Therefore the syringe containing Tc99m MAA should be vigorously shaken before injection. Moreover, at the time of injection, blood should not be withdrawn in the syringe.
   - Attenuation defects due to effusions: When the patient is scanned in the supine position, effusions may collect posteriorly/superiorly and mimic a defect.
   - Liver uptake: Xenon is fat soluble (somewhat soluble in blood) and may get deposited in the liver, especially in case of fatty liver.

ii. *Common causes of $\dot{V}/\dot{Q}$ mismatch:*
   - Pulmonary embolism: Impaired perfusion with normal ventilation. Fat emboli typically produce a mottled appearance due to the presence of many small fat emboli.
   - Pneumonia/pleural effusion/atelectasis: Usually, there is more ventilation abnormality with normal or minimally reduced perfusion.
   - Tumor/hilar lymphadenopathy: Bronchi are more resistant to extrinsic compression than are the pulmonary arteries because of their rigid cartilaginous rings.
   - Radiation treatment/vasculitis: Can reduce regional lung perfusion. Radiation treatment results in the obliteration of the microvasculature. Perfusion defects from radiation are usually geometric and follow the treatment port. They are typically nonsegmental. Ventilation may also be reduced in the irradiated area, but it is usually less affected than perfusion.
   - Pulmonary artery atresia or hypoplasia.
   - Segmental or branch pulmonary artery stenosis.
   - Fibrosing mediastinitis: Can lead to central vascular obstruction.

- AVM: Short circuit delivery of the particulate tracer to the regional pulmonary precapillary arterioles.
- CHF: Multiple nonsegmental perfusion defects can be seen.

iii. Causes of unilateral decreased perfusion:[8-10]

$\dot{V}/\dot{Q}$ scans can also show unilateral decreased perfusion in some conditions, which has been described below:

- Pulmonary agenesis: Absent ventilation, while X-ray chest may show a small, opaque hemithorax.
- Hypoplastic lung (pulmonary artery atresia): Usually ventilation to a small lung with no evidence of perfusion. On X-ray chest, the involved lung is usually small, hyperlucent and contains few normal pulmonary markings.
- Swyer-James syndrome: Characterized by bronchial destruction. It produces a more severe impairment of ventilation than of perfusion in the affected lung. Perfusion typically is decreased and inhomogeneous, but may be severely reduced and nearly unapparent.
- Tumor/mediastinal mass: A central mass can compress or occlude the pulmonary artery resulting in "absent" perfusion. Endobronchial obstruction can produce hypoxic vasoconstriction.
- Massive pleural effusion
- Pneumothorax
- Pulmonary embolism: Unilateral decreased perfusion can be secondary to Pulmonary Embolism (PE). Chronic PE has been shown to be the cause of unilateral hypoperfusion.
- Aortic dissection: Unilateral absent perfusion in the right lung due to direct compression of the right pulmonary artery by the intramural hemorrhage within the adjacent ascending aorta.
- Fibrosing mediastinitis: Vessels are occluded by progressive fibrosis prior to occlusion of the bronchi.
- Shunt procedures for congenital heart disease.
- Lung transplantation with nonperfusion of the native (diseased) lung.

Applications of Ventilation/Perfusion Scan

Ventilation and perfusion scans are applied in combination with chest X-ray for the diagnosis of pulmonary embolism, to evaluate integrity of the pulmonary alveolar membrane, quantification of lung perfusion prior to a planned pulmonary resection to determine the residual functional lung mass. Various pulmonary disorders in which lung perfusion scan is utilized are discussed below:

Pulmonary Embolism

Pulmonary embolism, a potentially fatal condition, is a frequently overlooked diagnosis, which can be associated with significant mortality if left untreated. More than 80% of deaths from PE occur in the first 30 minutes and 90% within the first two to three hours of the event.[10] It is commonly seen in bed ridden hospitalized patients. The common conditions predisposing to this entity are: Postoperative states especially following operations on the abdomen and pelvis; trauma, including fractures particularly of the lower extremities; neoplasms; prior history of thromboembolic disease; venous stasis; vascular spasm; intimal injury; hypercoagulability states and immobilization. In the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, 92% of the patients with pulmonary embolism had at least one of these above-mentioned risk factors.[11]

No single or combination of clinical findings is either specific or sensitive enough to diagnose or exclude PE. Most commonly, the emboli arise from the veins of lower extremity or the pelvis. Patients are usually present with acute onset breathlessness, pleuritic chest pain and rarely with hemoptysis. ECG findings may or may not be characteristic of PE. Diagnosis is straight forward in a patient with predisposing clinical problems and typical manifestations. When the clinical features are atypical, a high index of suspicion is required to diagnose pulmonary embolism. A chest X-ray at the time of presentation is often normal. Classic signs described in a chest X ray for PE are Hampton's hump (wedge shaped opacity above the diaphragm) and Westermark's sign (focal oligemia). Computed Tomography Pulmonary Angiography (CTPA) is being more frequently used nowadays at the emergency rooms for rapid diagnosis of PE. CTPA has a high negative predictive value. The ready availability of CT has resulted in the modality largely supplanting $\dot{V}/\dot{Q}$ scanning, but CTPA is less accurate in detecting sub segmental thrombi. There is an additional risk of excessive radiation exposure.[12,13] Breast irradiation from a $\dot{V}/\dot{Q}$ scan is approximately 0.2–80.9 mGy, which is less than 5% of the radiation dose to the breast resulting from CTA.[14] It has been determined that approximately 1 of the 300 women in the reproductive age group, who undergo CTPA, has a risk of developing carcinoma breast.[12] CTPA in addition, cannot be used in patients with previously known allergy to iodinated contrast agents and in patients with compromised renal function. Though presently under utilized, $\dot{V}/\dot{Q}$ scan offers the advantages of lower radiation exposure.

$\dot{V}/\dot{Q}$ scans: $\dot{V}/\dot{Q}$ scanning had been the mainstay for screening symptomatic patients for the presence of PE.

A Normal $\dot{V}/\dot{Q}$ scan essentially excludes the possibility of recent significant pulmonary embolus. Ventilation-perfusion mismatch (an area of normal ventilation corresponding to a segmental wedge-shaped area of decreased or absent perfusion) is the hallmark of a pulmonary embolism on $\dot{V}/\dot{Q}$ scanning.[13-22] $\dot{V}/\dot{Q}$ lung scan acquired within four to six hours of a large (lobar) embolism may show a matched defect due to vascular insult inducing reflex bronchoconstriction. In cases with high clinical concern for PE, SPECT images may help to better define the defect. The false-positive rate of high probability scans is only about 10%. In general, emboli are more frequent in the lower lobes due to the greater blood flow. Emboli are also frequently multiple (in 90%) and bilateral (in 85% of cases). Thus, unilateral decreased/absent perfusion to one lung is uncommonly the result of pulmonary embolism. Injection of Tc-99m MAA into the veins of the feet may help to reveal a DVT. Venous obstruction or collateral flow can be seen. Images recorded several minutes after the injection may also show hot spots where the Tc-99m MAA is adherent to thrombus in the vein.

Interpretation criteria: Traditionally, the $\dot{V}/\dot{Q}$ scans are interpreted using the PIOPED criteria, though original interpretation was based on Biello's criteria. In PIOPED criteria,[11, 15, 16] planar perfusion scan is compared with planar ventilation scan and interpreted along with a recent chest X-ray (<12 hours old). The perfusion defects are classified as small (<25% of a segment), medium (25% to 75%) and large (>75%) defects. Two or more large mismatched perfusion defects with a normal chest X-ray indicate the high probability of PE. One to three moderate-sized mismatched perfusion defects are considered as intermediate probability. Less than three small-sized mismatched perfusion defects are considered to be low probability. Modifications to PIOPED criteria were suggested on the bases of retrospective PIOPED data review. Gottschalk suggested that a high probability study should be interpreted as PE present and that normal and very low probability exams be interpreted as PE absent for a more conclusive interpretation. All other exams should be interpreted as PE uncertain. The modified PIOPED was based using this type of scheme.

PIOPED II study compared CTPA and $\dot{V}/\dot{Q}$ scan with pulmonary angiography as the gold standard.[17-20] PIOPED II concluded the superiority of CTPA against $\dot{V}/\dot{Q}$ scan. The main drawback of $\dot{V}/\dot{Q}$ scan as per this study was large number of indeterminate studies. The complicated probabilistic approach and results of PIOPED II study led to the decline in use of $\dot{V}/\dot{Q}$ scan. However, it is to be remembered that in PIOPED II, CTPA an inherently tomographic technique of was compared with technically inferior planar $\dot{V}/\dot{Q}$ scans. Alternatively the PISAPED (Prospective Investigative Study of Pulmonary Embolism Diagnosis) study proposed a simpler way of reading the lung perfusion scans. It proposed that a wedge-shaped perfusion defect of any size irrespective of the chest X-ray findings should be considered as indicative of PTE.[21] This approach led to the decline in the number of indeterminate scans. PISAPED criteria did not require ventilation scan. Recently $\dot{V}/\dot{Q}$ SPECT has been found to be as accurate as CTPA for diagnosis of PE.[22] Early reports of perfusion only SPECT/CT for diagnosis of PE on hybrid gamma cameras had appeared promising. $\dot{V}/\dot{Q}$ scan is also the investigation of choice in the women of reproductive age group in patients with renal failure and in patients with allergy to intravenous contrast agents.[23] Figure 29.3 is a

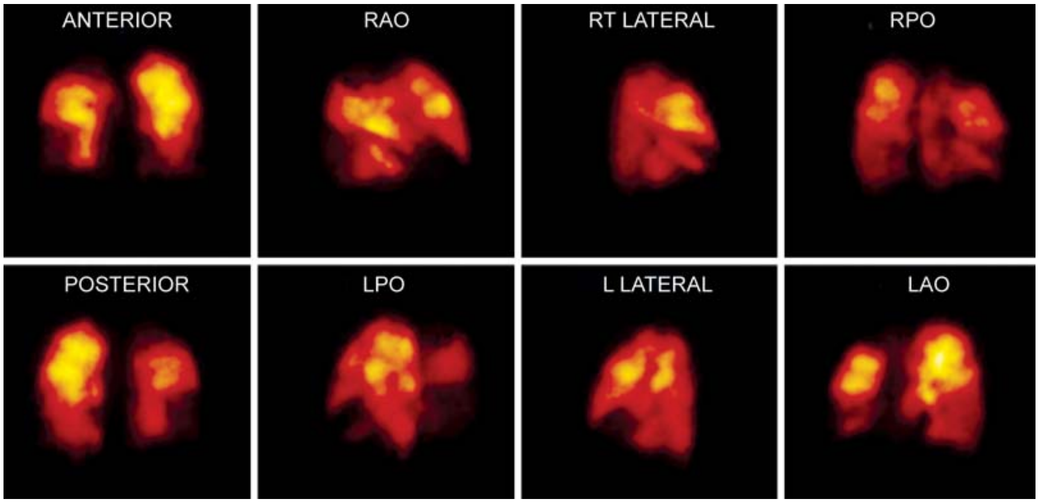

Fig. 29.3: Lung perfusion study with Tc99m-MAA (macroaggregated albumin) showing multiple large segmental perfusion defects in bilateral lungs, indicating high probability for pulmonary embolism

representative image of pulmonary embolism showing multiple perfusion defects.

In patients with prior pulmonary embolism having persistent ventilation-perfusion abnormalities, false-positive interpretation may be made. Pulmonary emboli resolve because of natural thrombolytic processes. A residual perfusion defect can be found in 9% to 30% of patients and incomplete resolution, more common in patients with an underlying cardiopulmonary disease.

Fat Embolism

Classically, a heterogeneous perfusion pattern (multiple small to moderate perfusion defects scattered throughout both lungs) is observed. Segmental perfusion defects are rarely present. However, in the majority of cases due to small-sized emboli, $\dot{V}/\dot{Q}$ scan may be normal. Unfortunately, the lung scan is not very useful in diagnosing fat emboli, but can be used to exclude thromboemboli as the cause of the patient's hypoxia in these patients.

Pulmonary Infarction

Pulmonary infarction may occur as a complication of PE. The perfusion defect is usually larger than the chest X-ray consolidation.

Pulmonary Hypertension

In secondary pulmonary hypertension, perfusion is typically heterogeneous, with small peripheral defects on $\dot{V}/\dot{Q}$ scintigraphy. However, the scan may also be normal. In primary pulmonary hypertension, the presence of reverse mismatch (diminished ventilation, normal perfusion) representing failure of hypoxic vasoconstriction has been described.[24] If extensive, this finding is of great physiologic importance as blood shunted through poorly ventilated lung tissue can be a major cause of hypoxia. In patients with primary pulmonary hypertension, HRCT demonstrates characteristic mosaic attenuation patterns. Areas of reverse mismatch on the $\dot{V}/\dot{Q}$ scan have been shown to correlate with the areas of increased attenuation on HRCT.[25]

Hepatopulmonary Syndrome

Tc99m-MAA imaging demonstrates heterogeneous pulmonary perfusion and the presence of right to left shunting (Fig. 29.4) with activity outside the lungs in the brain, liver and spleen. Scintigraphy can also be used to quantify the shunt, but it cannot distinguish between intracardiac and intrapulmonary shunting (best diagnosed by echocardiography with saline microbubble injection).

Hemoptysis

Labeled RBCs can also be used in cases of hemoptysis to localize the site of pulmonary hemorrhage. About 50% of patients may show positive scan and bleeding rates as low as 50 ml/day may be detected.

Emphysema

Multiple ventilation defects on the single breath view and abnormal retention on the washout study is visualized on Xenon-133 study in patients with emphysema. The late equilibrium images are typically normal as the gas slowly distributes via collateral airways into the abnormal regions. Due to the turbulent air flow, extensive central deposition of the tracer in the large airways may be seen on aerosol ventilation images. Asthmatic patient also demonstrate similar findings on ventilation images (Fig. 29.5). Xenon-133 has also been used to evaluate ventilation before and after lung volume reduction surgery in patients with pulmonary emphysema.[26] Regional ventilation can also be studied using Tc99m-DTAP aerosols.[27] Perfusion scan may be normal or near normal in early or mild COPD. With the progression of lung parenchymal destruction, matched nonsegmental ventilation-perfusion defects may be seen. Perfusion defects may also result from bullae themselves or by their compression of adjacent lung tissue. Reduced or absent perfusion in the upper lung zones is seen in the apical bullae.

Preoperative Evaluation of Regional Pulmonary Function

It is important to determine the risk of postoperative pulmonary insufficiency in patients with lung cancer. A forced expiratory volume in 1 second (FEV_1) > 2L or greater than 60% of the predicted value and FEV_1 > 1.5 or over 40% of predicted values are essential for pneumonectomy and lobectomy, respectively.[28] Lung scintigraphy provides a fairly accurate determination of the patient's ability to undergo surgery. The American College of Chest Physicians recommends that quantitative perfusion scintigraphy should be used in patients with borderline lung function to predict postoperative lung function.[29] Split function of each lung is determined from the geometric mean of counts obtained from both the anterior and the posterior lung perfusion images (Fig. 29.6). The postoperative FEV_1 can be calculated by

multiplying the global preoperative FEV_1 by the split function of the remaining lung. Ventilation scintigraphy may be a better predictor of postoperative function, but central airway tracer deposition can potentially limit the results.

Inflammatory Lung Diseases

Lung epithelial permeability can be evaluated by studying the clearance of inhaled Tc-99m DTPA aerosol from the lungs.[30-32] Clearance of the tracer is mainly dependent on the epithelial permeability and is only minimally flow dependent. Conditions disrupting the alveolar-capillary membrane, such as the Acute Respiratory Distress Syndrome (ARDS), hyaline membrane disease, sarcoidosis, idiopathic pulmonary fibrosis, systemic sclerosis or inhalational lung injury show rapid clearance of Tc99m-DTPA. Biexponential clearance is always abnormal and indicative of greater lung injury than mono-exponential clearance. In neonates, biexponential clearance curves are observed shortly after birth and become monoexponential after several days, possibly due to the maturation of the surfactant system. Normal Tc-99m DTPA clearance from the lungs is generally between 50 and 80 minutes (T½ approximately 60 minutes).[30] A normal clearance rules out inflammation in the lung from any cause.

Rapid clearance is also observed in active smokers. This is a generalized process throughout the lungs and is proportional to blood carboxyhemoglobin levels. The increased clearance rate is not influenced by the patient's overall smoking history, but rather by their immediate use. Clearance rates can return to normal within three to seven days after the cessation of smoking. Ventilated patients on Positive End Expiratory Pressure (PEEP) or high levels of O_2 (50%) also show more rapid alveolar clearance. Particle deposition in the airways will tend to slow the clearance rates. Patients with primary alveolar proteinosis or congestive heart failure with pulmonary edema also have reduced clearance rates. It is important to exclude extrapulmonary sites of activity (stomach, airways) from the region of interest when determining clearance rates.

Thrombus Imaging

Thrombus imaging may be performed by using either of the following tracers.[33-35]

- Tc-99m-apcitide (AcuTect)
- In-111 platelets
- Tc-99m Antiplatelet antibodies
- Radiolabeled fibrinogen
- Antifibrin antibodies
  - Antifibrin (T2G1s) antibodies F(ab)'2
  - Antifibrin DD-3B6/22 Fab'

Positron Emission Tomography

Positron Emission Tomography (PET) has virtually created a revolution in oncology imaging. F-18 FDG (2-fluoro-2-deoxy-D-glucose) is the most commonly studied PET agent used for the evaluation of malignant tumors. FDG competes with glucose for facilitated transport into tumor cells and also competes with glucose for phosphorylation by hexokinase. Unlike glucose, however, the phosphorylated form is not further metabolized and it gets trapped within the cell. Tumor cells show increased cellular uptake of FDG due to the increased number of surface glucose transport proteins (increased Glut-1 glucose transporter expression) and a higher rate of glycolysis in comparison to non-neoplastic cells. FDG uptake is related to the degree of cell differentiation and increased FDG uptake is generally associated with greater degrees of dedifferentiation. The highly sensitive functional information from PET scan is acquired now in combination with diagnostic quality CT scan for anatomical localization and interpretation.

Lung cancer is the leading cause of cancer death across the world, in part because the disease is usually diagnosed so late. F-18 FDG PET scan finds use in almost all the stages of lung cancer. PET/CT is more accurate with fewer equivocal findings and higher specificity than CT alone for char-acterizing pulmonary nodules. It is useful in the evaluation of a solitary pulmonary nodule measuring more than 8 mm.[36] In a patient with low clinical probability of malignancy, a negative PET scan has a high negative predictive value. The sensitivity of PET/CT for lung cancer is greater than 90%, therefore low to intermediate risk nodules that are metabolically inactive can be followed-up radiographically to ensure stability or resolution. Due to the FDG uptake in benign disorders, as well a positive PET scan in a clinically low-malignancy probability lesion, the patient has to be followed-up with biopsy. In a patient with a high preclinical probability of malignancy, direct biopsy has been found to be useful.

Both Non-Small Cell Carcinoma (NSCLC, squamous cell carcinoma and adenocarcinoma) and Small Cell Carcinoma (SCLC) are FDG avid. However, well-differentiated adenocarcinoma, carcinoid tumor and Bronchoalveolar (BAC) carcinoma show variable FDG uptake and may yield false-negative interpretation. PET is more sensitive than CT for staging of NSCLC, as well as for differentiating lung malignancy from benign lung findings such as postobstructive atelectasis.[37-39] PET scan has a higher diagnostic accuracy for the detection of metastasis in the mediastinal lymph nodes and the presence of distant metastasis (bone, adrenal glands, liver, etc). For stage I and II lung cancers, PET does not replace mediastinoscopy and biopsy. The false negative rate is still higher with PET scan compared with mediastinoscopy. PET is useful in differentiating stage III a (resectable disease) from Stage III b (unresectable disease). Published data indicates that PET/CT provides additional information in almost 40% of patients, with increased accuracy for T stage, as well as the N stage.[40] It is reported that PET/CT detected distant metastases in 92% of patients and was more accurate than CT alone. FDG-PET/CT has become an integral component of NSCLC staging because it improves the detection of nodal and distant metastases and frequently alters patient management (Figs 29.7 and 29.8). Magnetic Resonance Imaging (MRI) is the investigation of choice to detect cerebral metastasis though they may also be seen in a FDG-PET study. Since the FDG uptake is by the background normal brain, it is a less sensitive investigation for the detection of cerebral metastasis. Detection of recurrent disease is another situation in which PET/CT is useful. Recurrence if detected at a time when the disease volume is less, offers a chance for curative resection.

Differentiation of primary tumor (FDG avid) from atelectatic lung (less/non FDG avid) is an issue of concern in planning external beam radiotherapy for NSCLC. Often it is difficult to diagnose chest wall invasion in a case of NSCLC on CT scan. Use of radiation therapy for the curative treatment of lung cancer is limited by the radiosensitivity of surrounding normal structures. This

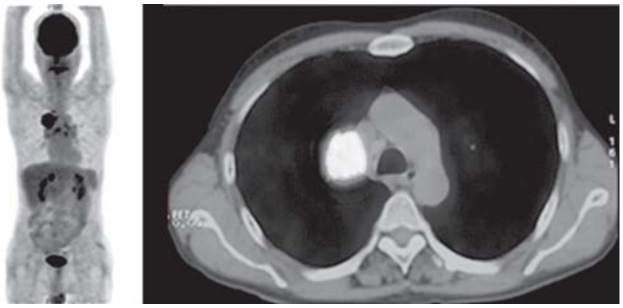

Fig. 29.7: Whole body F-18 FDG PET/CT image (MIP and Transaxial) in a patient with lung cancer showing the hypermetabolic lung tumor with no nodal or distant metastasis thereby enabling curative resection

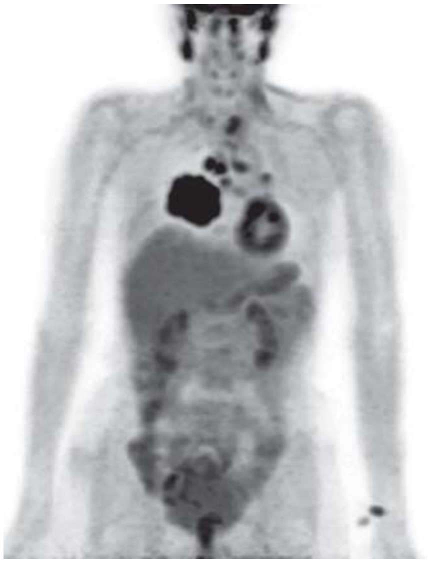

Fig. 29.8: Maximum Intensity Projection (MIP) image of F18-FDG PET/CT showing primary tumor in the right lung with multiple ipsilateral and contralateral mediastinal lymph nodal metastases. The contralateral mediastinal lymph nodes were missed on CT scan because they were sub-centimeter in size. Inclusion of PET prevented a futile thoracotomy

differentiation is easily possible on PET scan. Incorporation of FDG PET images into radiation therapy treatment planning resulted in a 15% to 60% increase or decrease in treated volumes.[41] In 30% to 60% of patients treated with definitive radiotherapy, PET simulation enhanced precision in coverage of the GTV.[42] PET/CT simulation for radiation therapy treatment planning requires the patient to be aligned using the same setup that will be utilized during radiation therapy. 4-D CT respiratory gating can also be utilized. 4-D radiotherapy using PET scan is the optimum method of delivering precisely targeted dose, avoiding normal tissues in the chest.

The assessment of response to therapy with conventional anatomical imaging modalities has inherent limitations. To assess response, for example by using the RECIST 1.1 criteria, a reduction in tumor volume/diameter is required. These changes are often difficult to appreciate on a CT scan and take longer time to become perceptible. Metabolic imaging with FDG PET/CT helps in an early assessment of response to therapy.[43, 44] PET scan is performed after 6–8 weeks of completion of chemotherapy and between 8–12 weeks after the completion of radiotherapy. As per the proposals of recent PERCIST criteria, the total disappearance of FDG avid disease is the complete metabolic response; a reduction of more than 30% in SUL (standardized uptake value) is considered as partial metabolic response; reduction of less than 30% in SUL is stable disease and appearance of new FDG avid lesions or increase in more than 30% is considered as a progressive disease.[45]

Most patients with SCLC have advanced metastatic disease at presentation. There are only a few studies on the role of PET scan in SCLC. These have shown some benefit in the terms of better staging of the patients and in the assessment of response to therapy.

Role of Cytology in Lung Lesions

Arvind Rajwanshi, Nalini Gupta

CYTOLOGICAL TECHNIQUES IN RESPIRATORY CYTOLOGY

Over the past two decades, there have been dramatic developments in the understanding of pulmonary disease, in the techniques available to identify, define, quantify and evaluate clinical signs and symptoms, radiographic and pulmonary pathology. Technological developments in recent years have rapidly increased the use of less invasive diagnostic techniques in medicine. This trend has influenced the practice of pathology by increasing the use of cytologic material for definitive diagnosis.

The major types of cytologic preparations that are used for the diagnosis of respiratory pathology in laboratories are:

1. Sputum
2. Bronchial washings and aspirates
3. Bronchial brushing
4. Bronchoalveloar Lavage (BAL)
5. Fine-Needle Aspiration Cytology (FNAC):
    - Transthoracic Fine-Needle Aspirations (TTNAs)
    - Transbronchial Fine-Needle Aspirations
6. Pulmonary microvascular cytology
7. Pleural aspirations
8. Imprint cytology of
    - Bronchial biopsy obtained by forceps on bronchoscopy
    - Lung biopsy obtained by transthoracic needle biopsy
    - Mediastinoscopic biopsy

Sputum

Although largely replaced by Fine-Needle Aspiration (FNA) and bronchoscopy, cytological examination of sputum for exfoliated malignant cells still is considered a valuable initial diagnostic test in patients presenting with a lung mass. Exfoliation of cancer cells in sputum from secondary tumors in the lung, is a rare phenomenon in current-day practice, with metastatic colonic adenocarcinoma seen most commonly. Sputum is a specialized product of the respiratory tract, which is the result of an interaction between the mucociliary apparatus and immune system against animate and inanimate invaders from the environment.[1]

A: Sputum may be obtained *spontaneously* or may be *induced*.

1. Spontaneous: Early morning deep cough sputum is taken.
2. Induced: Indicated when patient cannot produce spontaneous deep cough sputum.
   Inhalation of a solution stimulates mucous production. Usual solution used is 15% NaCl + 20% propylene glycol. Heated to 37^o C inhaled for 20 minutes.
3. Postbronchoscopy sputum

B: Sputum can be sent to the laboratory in a *fresh state*, in a *prefixed state*, in *saccomanno fixative* or in Cyto Lyt^R solution.

C: Number of samples: The optimum number of specimens to diagnose cancer is three, and to exclude cancer is five. By using five specimens, the detection rate (sensitivity) can be as high as 90 to 95%.[2,3]

D: Satisfactory specimen:

- For a sputum sample to be considered satisfactory, the sample should have:
  - Alveolar macrophages (dust cells)
  - Respiratory cells in induced sputum and sputum raised following bronchoscopy or other invasive procedures.

E: Impact of specimen collection on the morphology of diagnostic cancer cells: Cancer cells that are expectorated by coughing, originate from tumor close to the lumen of bronchi and from necrotic tumor cells which are discohesive. The diagnostic criteria like nuclear pyknosis in epidermoid carcinoma and nucleolar prominence in adenocarcinoma are actually artifacts due to degenerative changes. These changes can be appreciated in sputum and bronchial wash aspirates rather than bronchial brushing and FNACs. These artifacts are specific and constant enough for typing the tumor as squamous cell and adenocarcinoma respectively.

Bronchoscopy

Gustav Killian[4] in 19th Century developed the rigid bronchoscope to directly visualize the mucosal surface of bronchi and obtain samples for cellular evaluation.

Indications

- Evaluate lung lesions of unknown etiology which appear on X-rays as density, infiltrate, atelectasis or localized by unexplained hemoptysis.
- Origin of unexplained positive sputum cytology
- Stage lung carcinoma and evaluate response to therapy
- Obtain microbiological material for suspected pulmonary infections
- Diffuse and focal lung disease
- Investigate unexplained paralysis of vocal cord, superior vena cava syndrome, chylothorax or unexplained pleural effusion.

Fiberoptic bronchoscope permits the visualization of the lower respiratory tract and a variety of samples can be obtained by the following measures:

1. Bronchial aspirations and washings
2. Bronchial brushings of the suspected lesion
3. Bronchoalveolar lavage
4. Transbronchial fine needle aspirates
5. Imprint cytology of bronchial forceps biopsy.

Bronchial Aspirate and Bronchial Washings

i. *Bronchial aspirates* are obtained by introducing the bronchosope in the lower respiratory tract and aspirating the secretions by suction apparatus.

ii. *Bronchial washings* from the visualized areas are collected by instilling 3–5 ml of a balanced salt solution through the bronchoscope and reaspirating.

Bronchial Brushings

Cell samples are obtained with small brushes under visual control by fiberoptic bronchoscope or by employing imaging guidance technique.

Brushings should be done prior to biopsy procedure to prevent contamination of the specimen by blood.

Bronchoscopic Findings

It is very important to know the bronchoscopic findings before interpreting the bronchial brush cytology.

Bronchoscopy appearance	*Interpretation*
Pale pink:	Normal
Granulation tissue:	Inflammatory mucosal reaction
Irregularity of mucosa:	Early malignancy
Raised lesion:	Malignancy
Cauliflower like with pale yellow or white colour:	Squamous cell carcinoma
Mulberry:	Adenocarcinoma
Necrotic appearance of mucosa:	Small cell carcinoma
Narrowing of airway:	Extrinsic compression by mediastinal nodes

Forceps biopsy can be done for histopathology. Preceding the biopsy, an imprint cytology or "wash technique" (biopsy is put in normal saline, taken out to be sent for histology, while the saline is sent to the cytology lab) can be used and processed for cytology.

Complications:

- Bronchospasm
- Laryngospasm
- Pneumothorax
- Breaking of brushes and forceps
- Fever.

Bronchoalveolar Lavage (BAL)

Bronchoalveolar lavage is based on the concept that cells and noncellular components on the epithelial surface of the alveoli are representative of the inflammatory and immune systems of the entire lower respiratory tract. It is a relatively noninvasive means of sampling the representative cellular component in the alveolar and bronchiolar air spaces. The technique was initially introduced as a therapeutic procedure to remove accumulated secretions in diseases like alveolar proteinosis, cystic fibrosis and asthma. But over the years, this technique has proved to be of immense value in the diagnosis of the following disorders:[5]

1. Detecting opportunistic infections in immunocompromised individuals.[6]
2. Diagnosis and staging of interstitial lung diseases, such as:[7]
   a. *Specific interstitial lung diseases*
      I. Idiopathic pulmonary fibrosis (IPF)[8]
      II. Pulmonary fibrosis associated with collagen vascular disorders (PF-CV)
      III. Hypersensitive pneumonitis (HSP)
      IV. Extrinsic allergic alveolitis (EAA)
      V. Asbestos related interstitial disease
      VI. Silicosis
      VII. Beryllosis
      VIII. Sarcoidosis
      IX. Lipoid pneumonia[9]
   b. *Rare interstitial lung disease*
      I. Histiocytosis-X
      II. Chronic eosinophilic pneumonia[10]
      III. Alveolar hemorrhage: Hemosiderin-laden macrophages
      IV. Obliterative bronchiolitis
3. Detection of lung cancer[11]
   a. Bronchioloalveolar carcinoma
   b. Lymphangitic carcinomatosis

Technique and Processing

The middle lobe or lingula is lavaged routinely in the absence of any localized lesion. The tip of the bronchoscope is wedged into a subsegmental bronchus at the level of fourth or fifth branching. 0.9% sterile saline is inserted at room temperature and reaspirated in 20–50 ml aliquots. This is repeated five times at each site.

Lavage procedure is considered invalid if:

1. There is a presence of purulent secretions in the airways.
2. Bronchoscope is not maintained in wedge position during lavage.
3. Volume of fluid recovered is less than 40% of the volume infused.

Normal Constituents of BAL[12]

In a nonsmoker:

Alveolar macrophages	$\geq$ 85%
Lymphocytes	10-15%
Neutrophils	$\leq$ 1%
Eosinophils	$\leq$ 1%
Ciliated columnar cells	$\leq$ 2 %
T4 : T8 ratio	0 .9–2.5

In smokers, the cell yield is four times greater, with slightly increased number of neutrophils.

BAL: Cell counts are useful in the diagnosis and prognosis of certain disorders.

1. Cell Counts

The presence of increased nucleated cells is of no diagnostic or prognostic value. The reasons for increase in various types of inflammatory cells is shown in Table 30.1.

2. Diagnosis

- Infective agent
- Malignant cells

3. Diagnosis Aided by Special Stains, Additional Stains or Studies

- Langerhans cell histiocytosis (S100)
- Alveolar proteinosis (PAS)
- Pneumoconiosis
- Berylliosis – Positive lymphocyte transformation test

TABLE 30.1: Increase in inflammatory cells

↑ Lymphocytes	↑ Eosinophils	↑ Neutrophils
Sarcoidosis (active) (T4-T8↑) >1	Eosinophilic pneumonia	Collagen vascular disorders
Berylliosis Hypersensitivity pneumonitis (T4: T8 ↓) <1	Collagen vascular disorders	Idiopathic pulmonary fibrosis
Silicosis	Infection due to helminths, fungi	Bacterial and fungal infections
TB and viral infections	Asthma	Bronchitis
	Allergic broncho-pulmonary aspergillosis	Asbestosis and ARDS

4. Cell Counts in Evaluating Prognosis of the Disease

a. Idiopathic pulmonary fibrosis (IPF):
↑ T lymphocytes—good prognosis
↑ Eosinophils in IPF—poor prognosis
b. Collagen vascular diseases
↑ Neutrophils—presence of interstitial involvement
↑ Lymphocytes—clinically stable collagen vascular disease.
c. HSP—↑ T8 protects against pulmonary fibrosis
d. Sarcoidosis: Ratio T4:T8 normal—stable course of diseases
Ratio T4: T8—↑ deterioration in clinical course
BAL lymphocytes > 35% Poor response to therapy
BAL lymphocytes < 35% Good response to therapy
e. Asbestosis: Presence of asbestos body—indicates exposure
Asbestos body with increased lymphocytes, neutrophils and eosinophils indicates subclinical pulmonary involvement.
f. Berylliosis—similar to Sarcoidosis.

ASPIRATIONS

First report of needle biopsy of the lung was prepared by Leyden in 1883 who used it for the diagnosis of pneumonia. In 1886, Menetrier used it for lung cancer. In 1930, Martin and Ellis used this technique with the thin needle followed by Grover and Bindley in 1939.[13,14] X-ray enhanced television screen was used by Söderström in 1966, followed by Sinner and Nordenström in 1975.[15,16] Since most lung masses are carcinomatous in origin, depending on various factors (age, sex, smoking habit and size), the recommendation of FNA as the first line investigation warranted because of high yield to risk for complication ratio.[17]

A. Transbronchial Needle Aspiration (TBNA)

Transbronchial needle aspiration is a special modification of fine-needle aspiration for those cases in which lung neoplasm has not invaded the mucosa, and is therefore inaccessible by sputum or brushing washings.[18-20] This aspiration is done under bronchoscopic, fluoroscopic and Computed Tomography (CT) guidance and the samples are processed through conventional techniques.

Indications of TBNA

1. Mediastinum–diagnosis and staging of lung carcinoma
2. Hilar lesions
3. Intraluminal lesions which are necrotic (so as to sample non necrotic areas) or submucosal (carcinoids, bronchial gland tumor).
4. Parenchymal coin lesions
5. Pancoast tumor
6. Benign parenchymal lesions like sarcoidosis or other granulomatous conditions.

B. Transthoracic Fine-Needle Aspiration Cytology

In this technique, a fine needle (with external diameter 0.6mm, length 10-20 cms) is passed through the chest wall into the pulmonary mass, usually visualized by fluoroscopy or CT. Air dried and wet fixed smears are made from aspirated material and stained by May-Grünwald Giemsa (MGG) and Papanicolaou (PAP) stains.

If the lesion is very deep and small (≤ 2 cm), then wider bore needle with 0.9–1 mm external diameter should be used. If the lesion is hard and solid (Hamartoma and calcified granulomas), the "screw biopsy" is indicated, where a stylet with screw tip is introduced through the needle into the lesion and fixed, which facilitates penetration of the hard tumor by the needle.

Indications for TTNA: The main indication for TTNA is suspected lung cancer patient with negative results for malignant cells, on five consecutive sputum samples, bronchial brush or wash. Other indications are inoperable lung cancer, solitary pulmonary mass, multiple pulmonary masses, superior sulcus tumor, refusal to undergo exploratory thoracotomy, failure to respond to antitubercular therapy or suspected infectious process.

Contraindications:
- Debilitated uncooperative patients who have uncontrollable cough
- Vascular lesion, pulmonary hypertension, bleeding diathesis or anticoagulant therapy
- Echinococcus cyst.

Complications:
- Pneumothorax 2.6%[21]
- Air embolism
- Hemothorax
- Hemoptysis.

C. Pulmonary Microvascular Cytology

Pulmonary microvascular cytology is the examination of a blood sample drawn through a wedged pulmonary artery catheter to diagnose lymphatic carcinomatosis. The blood must be collected in a heparinized tube. In the laboratory, the specimen is placed on a Ficoll-Hypaque gradient to remove the blood and concentrate diagnostic cells.[22]

D. Pleural Aspirations

A proper cytopreparatory technique for effusions is very important for correct interpretation of the disease process occurring in the pleura. A poorly prepared smear causes diagnostic problems and may result in both false-positive and false-negative diagnosis.

To ensure an optimal cytopreparation, certain prerequisites should be fulfilled:

Immediate submission of unfixed specimen to the cytology lab with the immediate processing of the material is mandatory. The fluid is processed by *wet mount technique* where, one drop of centrifuged sediment is added to one drop of toluidine blue solution (0.5 mg of toluidine blue + 20 ml 95% alcohol, 80 ml distilled water)

This technique is performed for:

- Rapid diagnosis of malignancy
- Judge cellularity: If the specimens are very cellular, they should be stained separately to prevent cross contamination while poorly cellular specimens are processed by cytocentrifugation or filtration techniques.
- Ancillary tests: Additional smears may be prepared for special stains, flow cytometry and electron microscopy.
- Preparation of cell block for histochemical and immunohistochemial evaluation.

IMPRINT CYTOLOGY

Imprint can be made from bronchoscopic biopsies, obtained by forceps or transthoracic needle biopsy or mediastinoscopic biopsy. The smears are wet fixed and can be stained by Rapid H and E or PAP.

The sensitivity (tumor detection) and specificity (tumor typing) of sputum and BAL/ bronchial brushings is approximately 70 to 80%.

The sensitivity when all three (brush, biopsy, imprint) methods are used together may be as high as 97%; the specificity approaches 100%.[23]

ENDOSCOPIC ULTRASONOGRAPHY GUIDED FNA AND ENDOBRONCHIAL ULTRASOUND FNA

Endoscopic Ultrasonography (EUS) is a novel method for staging of the mediastinum in lung cancer patients. The recent development of linear scanners enabled safe and accurate FNA of mediastinal and upper abdominal structures under real-time ultrasound guidance.[24] EUS-FNA may replace CT-guided biopsies and reduce the number of exploratory thoracotomies.[25] Bronchoscopy can fail to establish a diagnosis in up to 30% of patients with suspected lung cancer. Intrapulmonary tumors located near or adjacent to the esophagus can be visualized and biopsied under real-time ultrasound guidance by EUS-FNA.[26] Endoscopic ultrasonography-FNA is a minimally invasive procedure that can be used as an adjunct or alternative to mediastinoscopy.[27] The technique is safe and it greatly reduces the number of surgical interventions.[28-30]

Endobronchial Ultrasound (EBUS) with real-time TBNA offers improved sensitivity and accuracy for staging of the middle mediastinum, and, combined with endoscopic ultrasound, should allow investigation of the majority of the mediastinum.[31-33]

INFLAMMATORY DISEASES OF THE LUNG

Acute Inflammation

Acute inflammation is characterized by the presence of neutrophils, histiocytes, debris, and necrosis in pneumonia, abscess and purulent bronchitis, resulting in tissue destruction.

Chronic Inflammation

Nonspecific

Nonspecific chronic inflammation is common.

Follicular Bronchitis

An abundance of immature lymphocytes can point towards follicular bronchitis. This should be distinguished from non-Hodgkin's lymphoma or small cell carcinoma.

Granulomatous Inflammation

Collections of epithelioid histiocytes along with giant cells indicate granulomatous inflammation (Fig. 30.1). In sputum, epithelioid histiocytes may be shaped like elongated cones that stain pink to orange when degenerated and look like carrots, hence are termed "carrot cells." These should be differentiated from bronchial epithelial cells, especially in bronchial brushings or aspiration cytology.

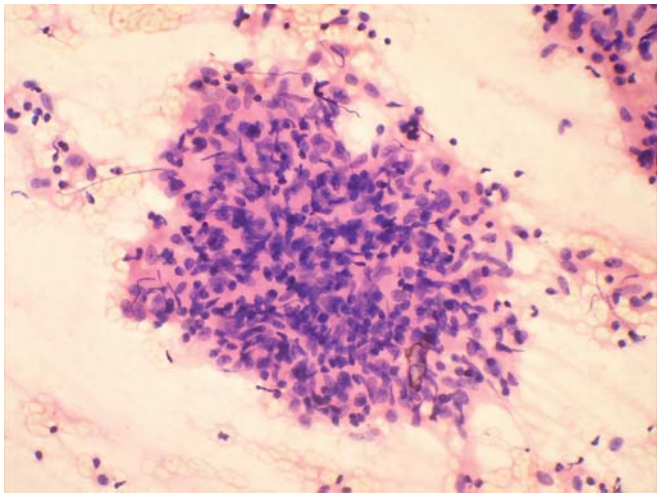

Fig. 30.1: Collection epithelioid cells and lymphocytes forming a granuloma (H and E, 20X)

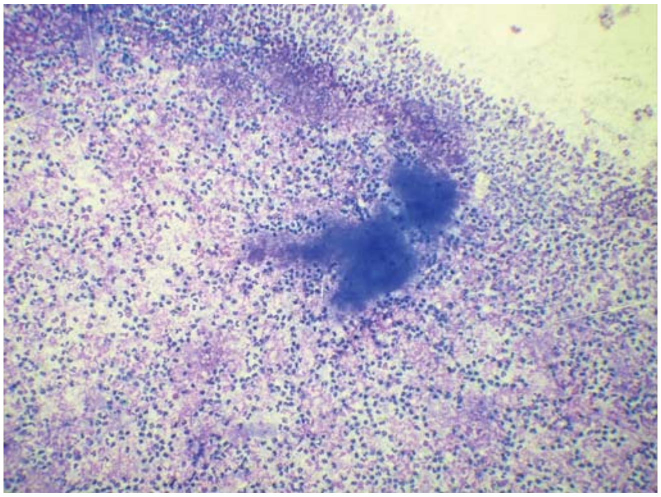

Fig. 30.2: Sheets of degenerated acute inflammatory cells in a necrotic background (MGG, 10X)

Tuberculosis

Epithelioid histiocytes, giant cells (Langhans' type), lymphocytes, and a necrotic caseous background is diagnostic of tuberculosis (Fig. 30.2).[34]

Giant cells are seen in sputum in up to half of cases of pulmonary tuberculosis, however, typical Langhans giant cells are present in only as few as 5% of cases.[35] In tuberculosis, epithelioid histiocytes are found in about 25 to 50% of sputum specimens.[36] In sputum specimens in which either Langhans giant cells or epithelioid histiocytes are seen, almost 60% of the patients have tuberculosis, depending upon the patient population.[37,38] Identification of beaded acid-fast bacilli or a positive culture clinches the definitive diagnosis of tuberculosis. The differential diagnosis of necrotizing granulomas includes fungal infections and Wegener's granulomatosis.[39]

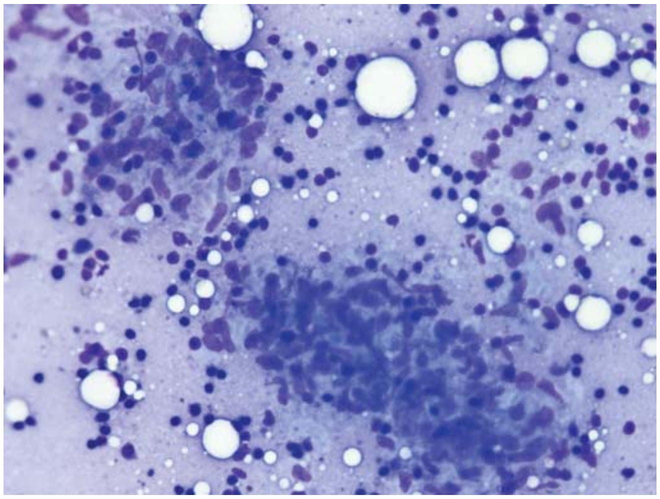

Fig. 30.3: Epithelioid cell collections along with lymphocytes in a case of sarcoidosis (MGG, 40X)

Sarcoidosis

It is a chronic granulomatous disease of unknown etiology. Epithelioid histiocytes or giant cells are seen with absence of caseation necrosis (Fig. 30.3).

Rheumatoid granulomas can also exfoliate epithelioid histiocytes with bizarre shapes. Background may have marked inflammation and necrotic debris.

Specific Infections

Cytologic methods are increasingly being used to diagnose opportunistic infections, especially in immunosuppressed patients.

Viral Pneumonia: Viral infections, such as cytomegalovirus are commonly seen in immunocompromised patients.[40] Viral infection can also cause reactive changes in bronchial cells and it becomes difficult to distinguish the same from bronchioloalveolar carcinoma.

Candida, Bacterial Colonies: First rule out oral contamination, overgrowth.

Miscellaneous Infections: Fungi, pneumocystis, toxoplasma, etc. mostly seen in immunosuppressed patients.[41-43]

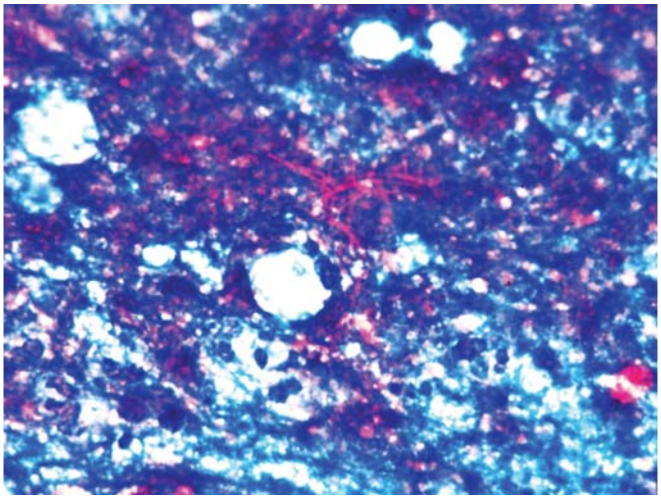

Fig. 30.4: Multiple thin long filamentous branching filamentous structures (Nocardia) in an inflammatory background (Modified Ziehl-Neilsen stain, 100X).

Hemophilus, *Staphylococcus* and *Streptococcus* species, *Klebsiella*, anaerobic, or mixed flora are common and can cause lung abscess.[44,45] Fungi, especially *Mucor* or *Aspergillus*, as well as *Actinomyces* or *Nocardia* (Fig. 30.4),[46,47] can also cause pulmonary abscesses.[48]

Reactive atypia and squamous metaplasia associated with epithelioid granulomas, particularly due to tuberculosis or *Aspergillus* can lead to a false-positive diagnosis of cancer.[49,50] And also, granulomas can coexist with cancer.

When an infectious disease is suspected, the left over sample should be submitted for cultures and special stains.[51] Culture in FNA specimens is a useful adjunct to diagnosis. This method can be used to triage patients with suspected infectious diseases and can aid in managing patients who may have recurrent infections.[52]

Echinococcus—is considered a contraindication to FNAC or biopsy.[53]

In lung FNA specimens, culture and special stains should be restricted to specimens with acute inflammation or necrosis. Gram's stain and fungal culture are insensitive and not cost-effective, and fungi are often identifiable with routine stains.[54]

Cytomegalovirus infection leads to presence of large cells with a nucleus having a large, smooth, amphophilic intranuclear inclusion (Fig. 30.5). The inclusion has a prominent halo, and thin strands of chromatin connect the inclusion with the inner nuclear membrane.[55]

Herpes simplex: Herpes simplex virus pneumonia is a disease of immune compromised individuals. It is characterized by intranuclear inclusions with nuclear enlargement with basophilic ground-glass alterations in the nucleoplasm. Later, the inclusions may coalesce to form single eosinophilic inclusion body surrounded by a halo.

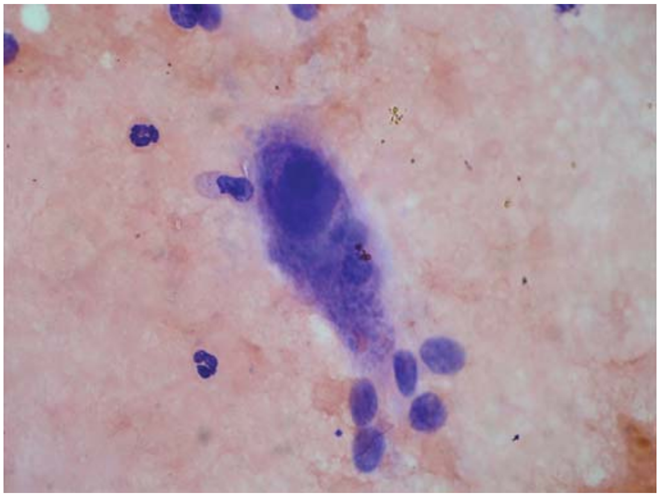

Fig. 30.5: A single cell showing marked nucleomegaly with a basophilic nuclear inclusion in a case of CMV infection (MGG, 100X)

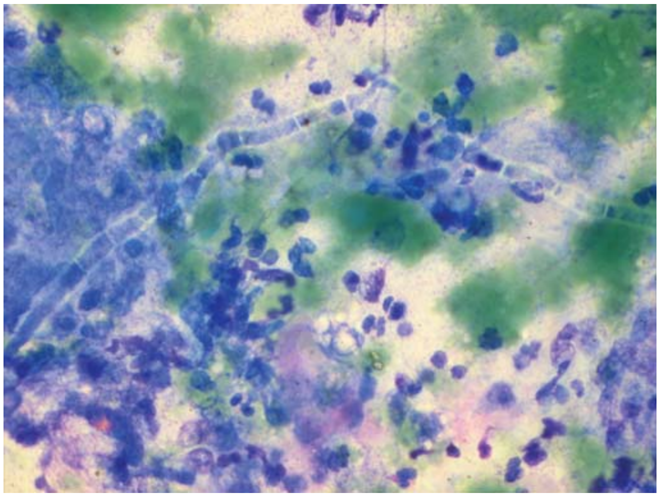

Fig. 30.6: A long septate hyphae with parallel cell walls of the fungus-aspergillus in a necrotic inflammatory background (MGG, 40X)

Aspergillus (fumigatus, niger) is characterized by 45° angle branching of true, septate fungal hyphae of 3 to 6 µm uniform width (Fig. 30.6). Fruiting bodies (conidiophores) are rarely seen.

Coccidioides (immitis) is marked by nonbudding, thick-walled spherules, measuring 20 to 60 µm and round, nonbudding endospores measuring 1 to 5 µm.

Cryptococcus (neoformans) organisms measure 5 to 20 µm and have a very thick, gelatinous capsule which stains

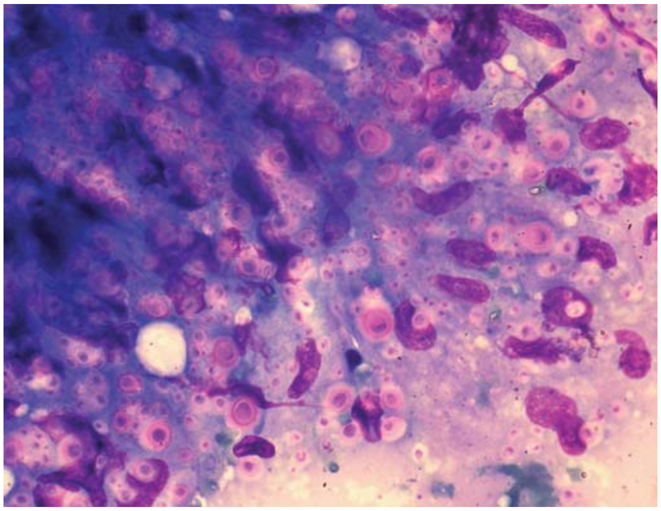

Fig. 30.7: Many extracellular organisms of varying sizes 5 to 15 mm in diameter with evidence of budding in a case of Cryptococcosis (MGG, 100X)

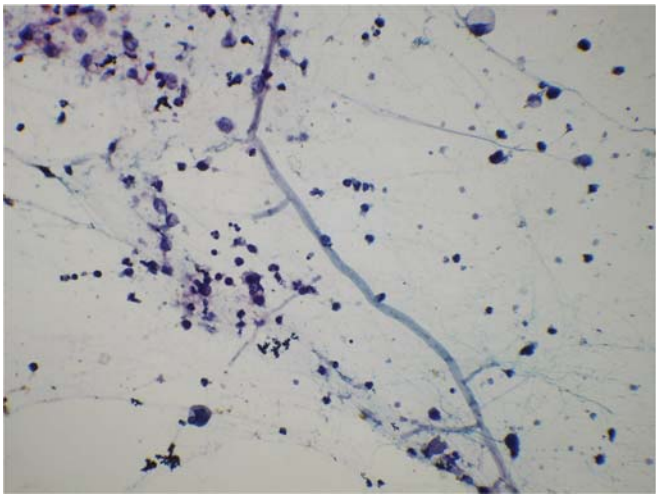

Fig. 30.9: Mucormycosis-Broad (from 5–20 µm), irregular, thin-walled, folding on themselves, ribbon-like, aseptate hyphae that branch at irregular intervals, often at 90° angles (PAP, 40X)

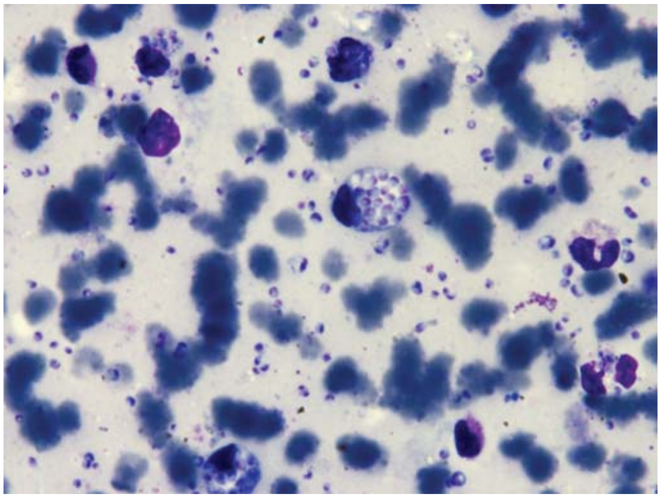

Fig. 30.8: Numerous round to oval, 2–4 µm in diameter, budding yeasts of Histoplasma present both extracellularly as well as intracellularly within histiocytes (MGG, 100X)

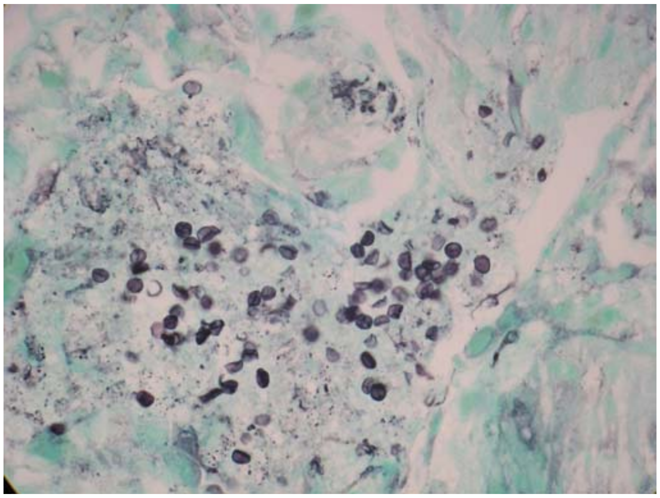

Fig. 30.10: Many cysts, 4 to 8 µm in diameter and spherical to cup shaped in a case of *Pneumocystis jeroveci* (Methenamine Silver stain, 100X)

well with special stains, such as mucicarmine, alcian blue or PAS. Single, teardrop-shaped budding is quite characteristic (Fig. 30.7).

Histoplasma (capsulatum) is a round to oval, budding yeast, measuring 1 to 5 µm which should be identified within cytoplasm of a histiocyte or neutrophil to be diagnostic (Fig. 30.8).

Zygomycetes (*Mucor*, *Rhizopus*, etc.) exhibit broad (from 5–20 µm), irregular, thin-walled, folding on themselves, ribbon-like aseptate hyphae that branch at irregular intervals, often at 90° angles (Fig. 30.9).

Pneumocystis jeroveci is seen more commonly in patients with acquired immunodeficiency syndrome.[56] Organisms are seen in foamy/flocculent alveolar casts (rounded masses of organisms). In GMS, the cell wall of the cyst stains black, often with a central dark dot. Cysts are 4 to 8 µm in diameter and spherical or cup shaped (Fig. 30.10). Trophozoites can be upto 8 per cyst, are about 0.5 to 1.0 µm in diameter. Trophozoites stain in Romanovsky (tiny purple dots).

Echinococcus granulosus (hydatid disease) is considered a contraindication due to possible anaphylaxis. Hydatid

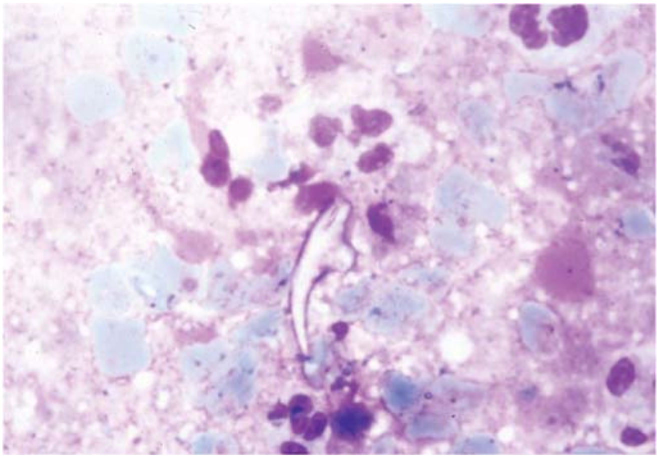

Fig. 30.11: Hooklet of hydatid in a necrotic background (MGG, 100X)

"sand" aspirated from a hydatid cyst shows both scoleces of *Echinococcus* and their hooks (Fig. 30.11).

NEOPLASTIC LESIONS OF THE LUNG

Cytological Classification of Lung Tumors

1. Squamous cell carcinoma
   - Well differentiated
   - Poorly differentiated
2. Small cell carcinoma
   - Oat cell type
   - Intermediate cell type
3. Adenocarcinoma
   - Well differentiated
   - Poorly differentiated
   - Bronchoalveolar
4. Large cell carcinoma
   - Giant cell type
5. Adenosquamous carcinoma
6. Carcinoid tumor
7. Adenoid cystic carcinoma[57]
8. Mucoepidermoid carcinoma
9. Carcinosarcoma
10. Others

However, there is also concept that diagnostic binary categorization of lung carcinoma into small cell carcinoma versus non-small cell carcinoma and evaluation of tumor stage have the only real significant effect on current patient management.

Squamous Cell Carcinoma (SCC)

This is the commonest tumor of the lung, but its incidence is decreasing.[58] It is strongly associated with cigarette smoking. Most SCC arises in the mucosa of the larger bronchi and therefore are generally located in the perihilar or central area.[59]

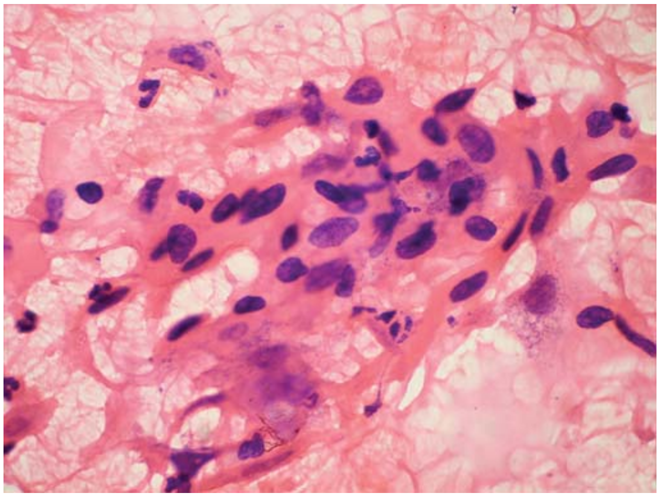

Fig. 30.12: Keratinized highly pleomorphic squamous cells with irregular shapes and staining reactions with many spindle shaped cells (H and E, 40X)

Cytologically, the tumors may be composed of large, pleomorphic to bizarre, poorly cohesive cells to small, uniform and cohesive cells. The nuclei of the cells show hyperchromasia, pyknosis and a coarse chromatin (Fig. 30.12). A typical background may consist of many degenerated cells with blurred outlines and the malignant cells.

The differential diagnosis of Non-keratinising SCC with poorly differentiated adenocarcinoma may be difficult. Very poorly differentiated SCC should also be distinguished from small cell carcinoma. Benign reactive changes due to infectious agents, particularly tuberculosis or fungi, or infarction, can mimic squamous cell carcinoma.

Adenocarcinoma

Adenocarcinoma is the most common primary peripheral lung cancer and occurs more commonly in nonsmokers. Scars in lung cancer have been classically associated with adenocarcinoma. Two basic types of adenocarcinoma are: (1) bronchogenic, the more common type, arising from or mimicking bronchial glands or mucous goblet cells, and (2) Bronchioloalveolar Carcinoma (BAC).[60]

Adenocarcinoma can show a wide range of differentiation, from very well differentiated to anaplastic and finally giant cell carcinoma.

Cytologically: The tumor cells can be singly scattered or tightly clustered. The key diagnostic feature is the

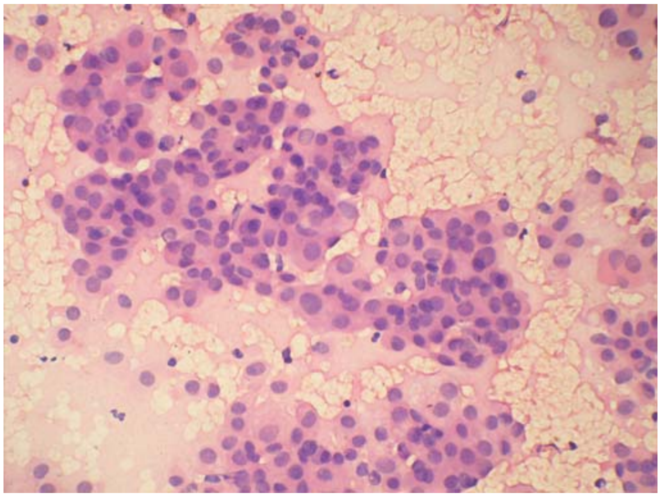

Fig. 30.13: Flat monolayered sheets or cell clusters of regular, small to intermediate sized cells with moderate cytoplasm and fine chromatin (H and E, 40X)

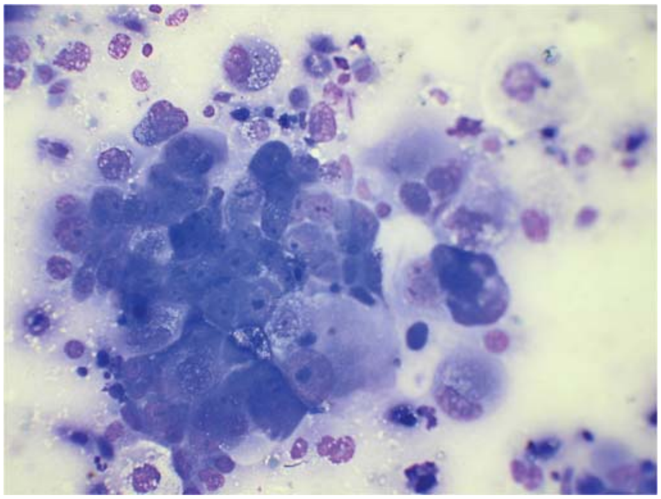

Fig. 30.14: Loosely cohesive cluster of malignant cells with moderate amount of vacuolated cytoplasm, coarse chromatin and prominent nucleoli (MGG, 100X)

formation of glands or papillae, or evidence of mucin production by the malignant cells. The cells are large with classical parameters of malignancy including variable size and shape, coarse chromatin and prominent nucleoli (Figs 30.13 and 30.14). The cytoplasm is pale gray thin and sparsely vacuolated, at times it may be abundant. Two basic subtypes of BAC are mucinous (secretory) and the more common non-mucinous (nonsecretory or serous).[61] Subtyping is based on the quality of the cytoplasm, but there is a significant degree of overlap in the cytological features.[62]

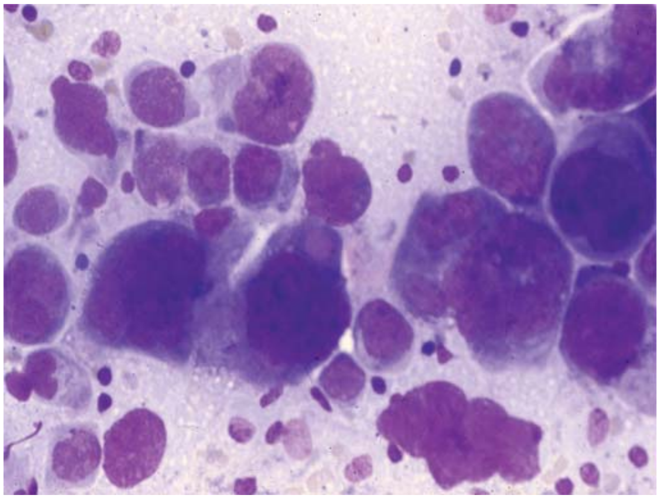

Fig. 30.15: Dispersed population of obviously malignant cells in a case of large cell anaplastic carcinoma (MGG, 100X)

In bronchoalveolar carcinoma, the cells are tall and columnar with anaplastic changes and at times may be confused with metastatic colonic adenocarcinoma.

The differential diagnosis includes large cell undifferentiated carcinoma, metastatic adenocarcinoma and non-keratinizing SCC. Benign reactions due to pneumonia; infarcts; or physical, chemical, or infectious agents can also lead to false-positive results.

Large Cell Undifferentiated Carcinoma

Most of these tumors occur in men and are associated with smoking. These grow rapidly and have poor prognosis. These types of tumors yield irregular groups and dispersed population of obviously malignant cells (Fig. 30.15). The texture of nucleus is finely granular with gray blue cytoplasm. The cells are generally in groups and consist of cell population with large irregular, single nucleus or multinucleation may be seen.

Small Cell Carcinoma

It is thought to arise from primitive cells that have the capacity for Kulchitsky (neuroendocrine) cell differentiation. Small cell carcinoma has the strongest relationship to cigarette smoking and rarely occurs in nonsmokers.[63,64]

Small cell carcinoma is usually centrally located. The tumor characteristically metastasizes extensively to hilar and mediastinal lymph nodes.[65] Fine-needle aspiration cytology is accurate and reliable in the diagnosis of small cell carcinoma.[66,67]

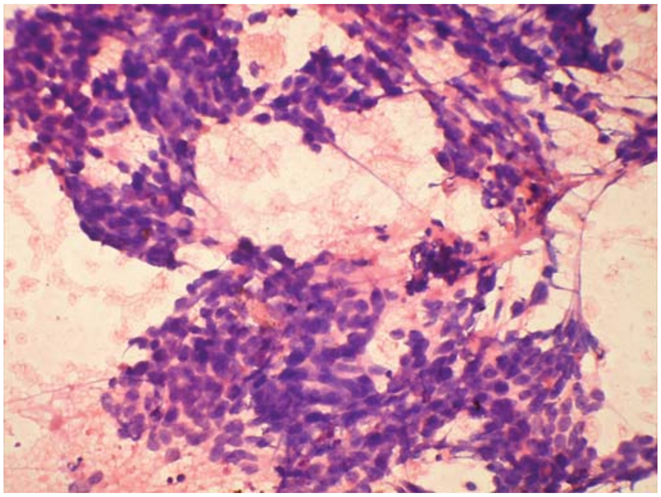

Fig. 30.16: Pleomorphic poorly cohesive cells with little or no cytoplasm and prominent crushing artifact (H and E, 40X)

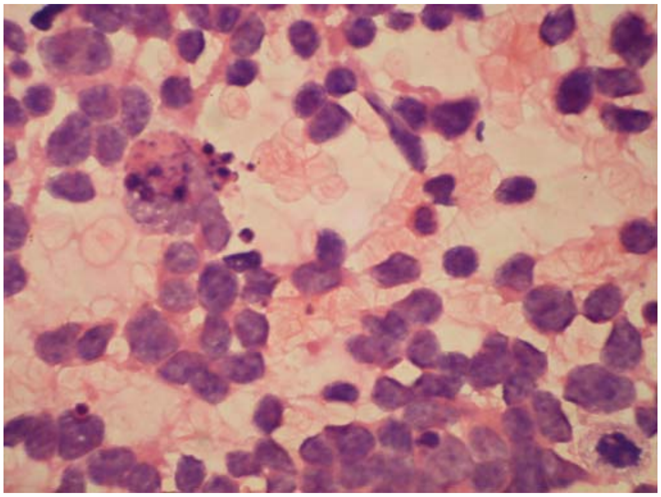

Fig. 30.17: Pleomorphic poorly cohesive cells with absent cytoplasm, nuclear molding, tear drop cells and inconspicuous nucleoli (H and E, 100X)

The aspirated material is abundant and semisolid. The smears are thick and the cells are easily traumatized. The cells have superficial resemblance to lymphocytes but are large round to oval or elongated. They form clusters and have classical tendency towards molding or "Indian file pattern." Crush artifact is quite characteristic of small cell carcinoma in FNA biopsy specimens (Figs 30.16 and 30.17). Small cell carcinoma usually demonstrates features of neuroendocrine origin immunocytochemically, including neuron-specific enolase, neurofilament proteins, synaptophysin, Leu-7, and sometimes chromogranin, and may also be positive for keratin.[68]

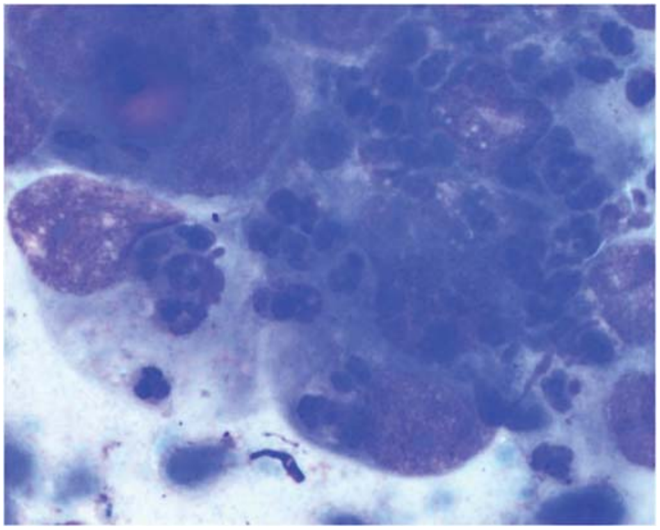

Fig. 30.18: A cluster of obviously malignant cells with marked pleomorphism admixed with polymorphs (MGG, 100X)

The differential diagnosis includes a carcinoid, poorly differentiated squamous and adenocarcinoma, non-Hodgkin's lymphoma or malignant small blue round cell tumors.

Giant Cell Carcinoma

Giant cell carcinoma comprises a heterogeneous group of tumors. Mostly occurs peripherally. This tumor may be a dedifferentiated adenocarcinoma or SCC; a subset of large cell undifferentiated carcinoma; or a specific entity not directly related to other types of lung cancer. Cytologically, smears show the presence of a significant number of multinucleated malignant tumor giant cells with obvious malignant atypia (Fig. 30.18).[69] These tumors are typically associated with neutrophillic infiltration along with prominent neutrophilic phagocytosis by tumor cells (Fig. 30.19).[70]

Neuroendocrine Tumors of the Lung

The following tumors are encountered in this category:

- Typical carcinoid tumor: Central, oncocytic and peripheral types
- Atypical carcinoid tumor
- Large cell neuroendocrine carcinoma
- Small cell carcinoma with neuroendocrine features.

Carcinoids account for about 5% of cases of lung cancer.

Central Carcinoid Tumor

Central carcinoid tumor usually presents with a slow-growing polypoid mass within a major bronchus, can be

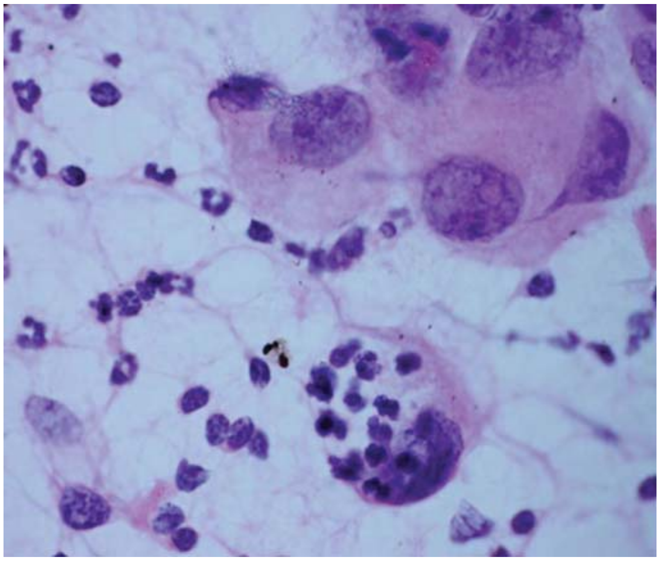

Fig. 30.19: Tumor cells showing neutrophilic phagocytosis in a case of giant cell carcinoma lung (H and E, 100X)

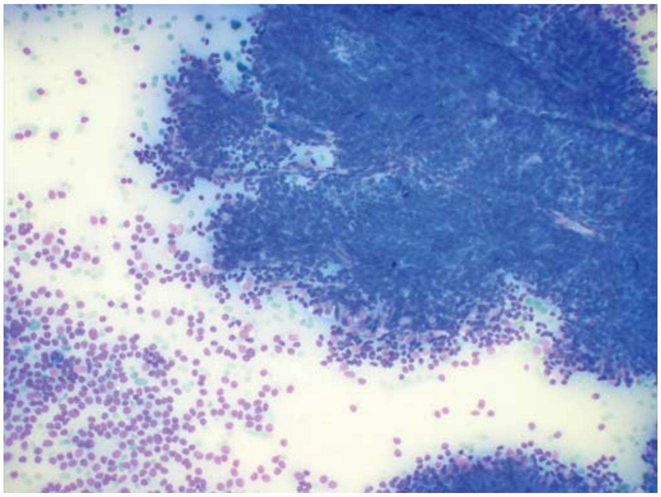

Fig. 30.20: A highly cellular smear showing tumor cells with prominent pericapillary arrangement and dispersed tumor cells (MGG, 10X)

non-hormone producing tumor, and some produce carcinoid syndrome. It is common in young adults and children. Infiltration in the surrounding tissues from the bronchus may occur. Cytologically, it shows a loosely cohesive population of monotonous cells (Fig. 30.20).[71] Rosettes, palisades or small clusters may also be seen. If there is extensive crush artifact, confusion with small cell carcinoma may occur.

Metastases to regional lymph nodes are occasionally reported in about 5% cases. Rarely metastases in bones occur which are of osteoblastic type. Surgery is the treatment of choice and the prognosis is excellent.

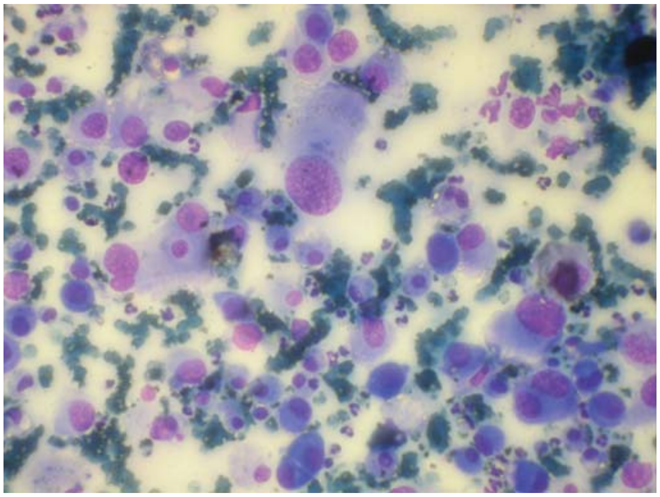

Fig. 30.21: Dispersed population of tumor cells exhibiting sudden anisonucleosis, eccentrically placed nuclei with stippled chromatin and prominent nucleoli (MGG, 40X)

Oncocytic carcinoid is a variant of central carcinoid in which the tumor cells have abundant, granular acidophilic cytoplasm. Electron microscopy shows numerous mitochondria with dense core secretory granules.

Peripheral Carcinoid Tumor

Peripheral carcinoid tumor usually occurs in peripheral lung beneath pleura and is discovered incidentally. Peripheral carcinoids tend to be more aggressive than central carcinoids, especially when the tumor is composed of spindle cells.[72] Pleomorphism and mitosis are present. The prognosis is excellent after surgical removal.

Atypical Carcinoid Tumor

This type of tumor possibly represents a link between typical carcinoid tumor and small cell carcinoma. These have been associated with smoking.[73] Cytologically, the tumor cells are larger than those of either typical carcinoid or small cell carcinoma (Fig. 30.21). Single cells are present with atypical features like increased mitosis, necrosis and nuclear hyperchromasia. Extensive metastasis occurs in lymph nodes. The behavior is aggressive.

Pulmonary Hamartoma

Hamartoma accounts for about 75% of benign lung tumors. It is usually solitary and presents as an asymptomatic clear cut small shadow just beneath the pleura in the lung parenchyma. Radiologically, calcification is seen

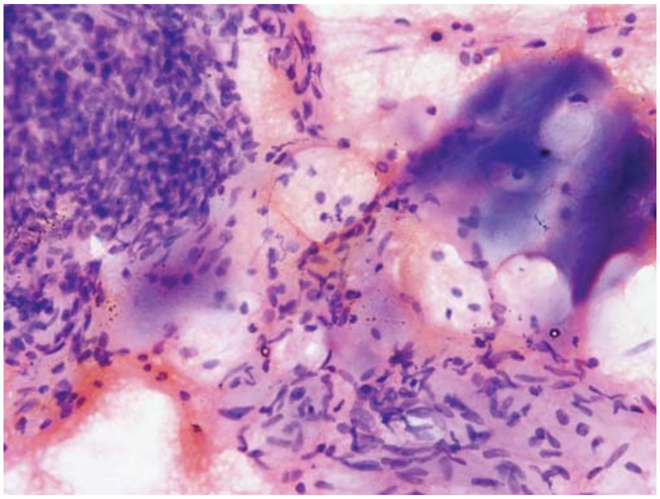

Fig. 30.22: Chondroid and adipose tissue fragments along with bland spindle-shaped cells and scattered benign epithelial cells in pulmonary hamartoma (H and E x40X)

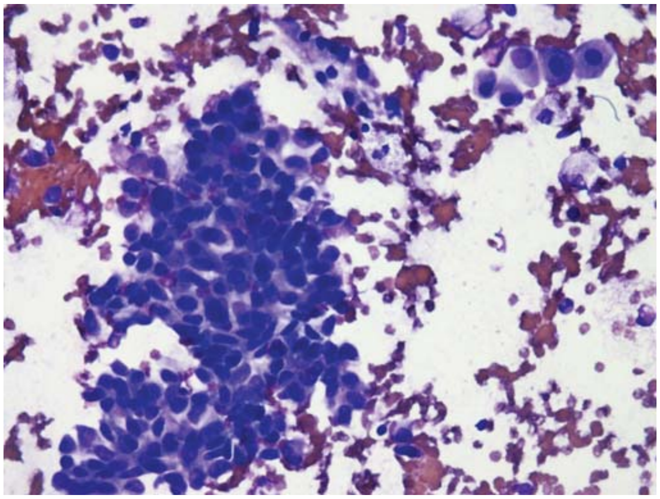

Fig. 30.23: Sheets and single oval to spindle cells in a bloody background with histiocytes in a case of sclerosing hemangioma (MGG, 40X)

which may be of popcorn type. Cytologically, the key diagnostic feature is the presence of cartilaginous or fibromyxoid fragments. Immature cartilage or fibromyxoid matrix, characteristically has wispy, frayed or irregularly feathered outlines (Fig. 30.22). It stains variably, but is usually basophilic in PAP and intensely metachromatic (magenta) in Diff-Quik.[74,75]

Grossly, it is sharply delineated and lobulated. Cut surface shows glistening cartilage with cleft. Microscopy shows cartilage, fat, smooth muscle and the clefts are lined by respiratory epithelium. The cartilage may be calcified or ossified. The lesion is acquired and represents primary overgrowth of mesenchymal tissues with secondary entrapment of bronchial epithelium. The treatment is conservative surgery in the form of wedge resection.

Inflammatory Pseudotumor

Inflammatory pseudotumors are quite rare and include fibroxanthoma (xanthogranuloma) and plasma cell granuloma. These are mostly asymptomatic, slow-growing, well-circumscribed, small peripheral lung masses.[76] Cytological features are nonspecific and may show admixture of plasma cells, lymphocytes, eosinophils, neutrophils, mast cells, histiocytes and myofibroblasts.[77] These cells can be seen in varying proportions. The stroma can be edematous to myxoid to fibrous to hyalinized. Excision is curative.

Sclerosing Hemangioma (Type II Pneumocytoma)

It is a rare, benign tumor of the lung. This occurs frequently in women (4:1). This tumor is usually solitary and located near the pleura with a predilection for the lower lobes. Cytosmears show abundant material in the form of sheets or single cells in a bloody background. Finding in aggregates of cells surrounding small blood vessels or sclerotic cores is characteristic (Fig. 30.23).[78]

Salivary Gland Analog Tumors

These probably arise from submucosal bronchial glands, the pulmonary counterpart of minor salivary glands. Mostly occur in the main bronchi.

Adenoid cystic carcinoma is the most common tumor which usually occurs in a major bronchus. On FNAC, smears show bland, uniform cells with scant cytoplasm.[79] The cells can be present singly or form tight, globular, honeycomb arrangements. The characteristic feature is the presence of mucoid (basement membrane) material, which is seen as rounded, acellular balls or cylinders, sometimes surrounded by tumor cells (Figs 30.24 and 30.25).

This material is transparent and lightly cyanophilic in Papanicolaou, but is brightly metachromatic (magenta) in Diff-Quik.

Mucoepidermoid carcinoma (MEC) of the lung can be high or low grade. On FNAC, the smears may show variable numbers of three cell types: mucus-secreting glandular cells, squamous cells and intermediate cells.

Pulmonary Blastoma

Pulmonary blastoma is also known as peripheral carcinosarcoma of embryonal type, or embryoma and can

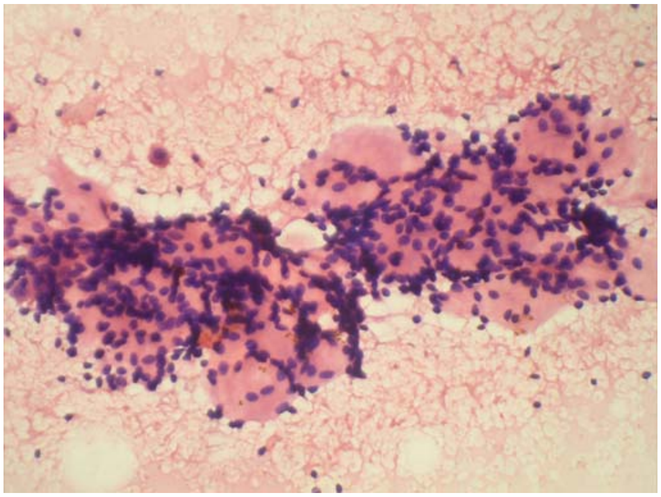

Fig. 30.24: Small uniform cells with hyperchromatic nuclei embedded in hyaline stromal globules in a case of adenoid cystic carcinoma (PAP, 40X)

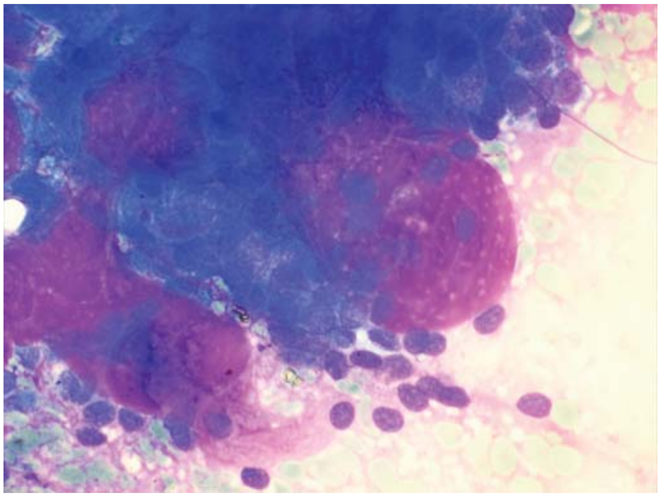

Fig. 30.25: Tumor cells embedded in metachromatically staining hyaline stromal globules (MGG, 100X)

occur at any age. The average age of diagnosis is about 40 years with male to female ratio being 3:1. This is usually located peripherally, but is rarely found intrabronchially. Microscopically, the tumor is reminiscent of fetal lung, the pulmonary counterpart of Wilms' tumor. Fine-needle aspiration cytology shows a biphasic epithelial and spindle cell growth pattern (Fig. 30.26). The cells of the epithelial component are cuboidal to columnar and may be present in sheets, acini or three-dimensional glandular structures. The cytoplasm usually contains glycogen vacuoles, which may give the cells a clear appearance. The nuclei are round to variable depending on the degree of differentiation of the tumor.

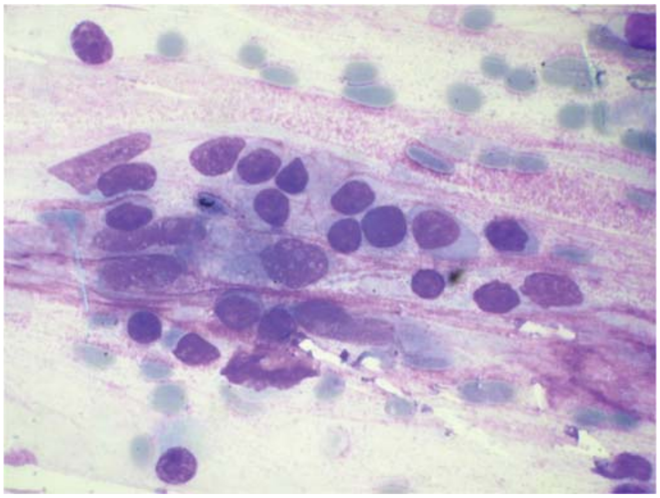

Fig. 30.26: A biphasic epithelial and spindle cell pattern in a case of pulmonary blastoma (MGG, 100X)

The sarcomatous component is usually cellular or myxoid malignant stroma composed of monotonous, small spindle mesenchymal cells (blastemal cells). The nuclei are slightly irregular with fine chromatin and indistinct nucleoli and scant cytoplasm.[80]

The differential diagnosis includes small cell carcinoma, large cell undifferentiated carcinoma or sarcoma, and the features sometimes overlap with those of carcinosarcoma.

Carcinosarcoma

This tumor usually occurs in adults, on average 10 to 20 years later than pulmonary blastomas. Most cases of carcinosarcoma are located centrally and have a worse prognosis. Fine-needle aspiration cytology shows a biphasic pattern of epithelial and spindle elements. The cells tend to be more intermixed and in majority of these tumors, the epithelial component is represented by non-keratinizing squamous cell carcinoma, but can also be adenocarcinoma or undifferentiated carcinoma.[81] The sarcomatous component usually resembles a fibrosarcoma or malignant fibrous histiocytoma. Occasionally, foci of chondrosarcoma, osteosarcoma, rhabdomyosarcoma or angiosarcoma may be seen and osteoclastic giant cells may also be present.[82] The differential diagnosis includes squamous cell carcinoma, non-small cell carcinoma, large cell undifferentiated carcinoma, giant cell carcinoma and pure sarcoma.[83]

Lymphoma

The lymphomas arising in the respiratory tract are rare. The mediastinum is more often involved. The primary lymphoma of this area can be diagnosed by cytological examination or FNAC. The criteria applied are same as described for other organs. The cells in malignant lymphomas are monomorphic, round and sometimes with anaplastic features. Primary Hodgkin's disease is exceedingly rare; however the metastatic lesions are more often seen.

Vascular Tumors: These tumors in lung are extremely rare and include hemangioma, hemangiopericytoma, angiosarcoma, lymphangioma and epithelioid hemangioendothelioma. Epithelioid hemangioendothelioma presents as multiple nodules. Cytologically, the smears may be hemorrhagic and may show loosely cohesive clusters of plump acidophilic endothelial cells. The tumor grows in slow fashion and remains restricted to thoracic cavity. The subtyping of these tumors is difficult in cytology because of compromised aspirated material in majority of cases and considerable cytomorphological overlap.

Primitive Neuroectodermal Tumor (PNET)

The term PNET is used to include a variety of tumors which may include malignant small cell tumor of the thoracopulmonary region (Askin's tumor). The immunocytochemistry and immunophenotyping can be applied to these malignant tumors to categorize them.[84]

Fine-needle aspiration cytology smears show small cells in small clusters or discrete cells. The cells are small monotonous primitive cells with scanty cytoplasm. The nuclei are round to oval with inconspicuous nucleoli. Rosette formation is a common feature (Figs 30.27 and 30.28). These rosettes may be focally present and careful search is required to locate them.

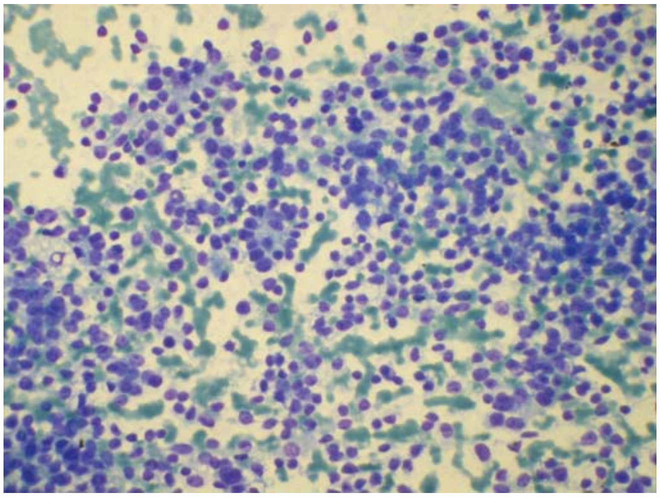

Fig. 30.27: Cellular smear with dispersed population of round cells with coarse chromatin and occasional rosette formation (MGG, 20X)

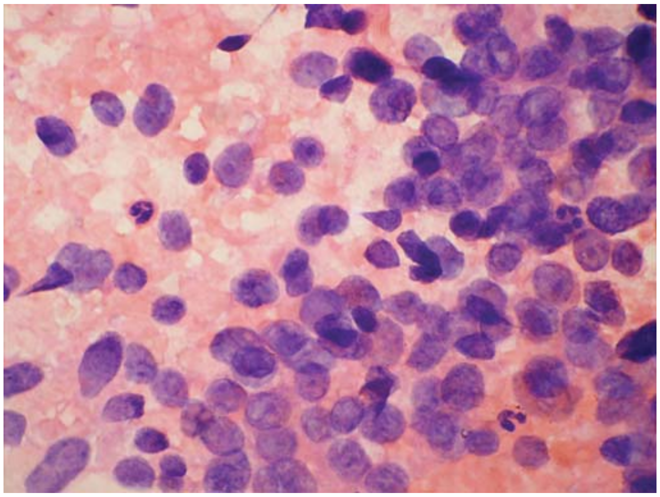

Fig. 30.28: Small round cells with coarse chromatin and occasional conspicuous nucleoli in a case of Askin's tumor (H and E, 100X)

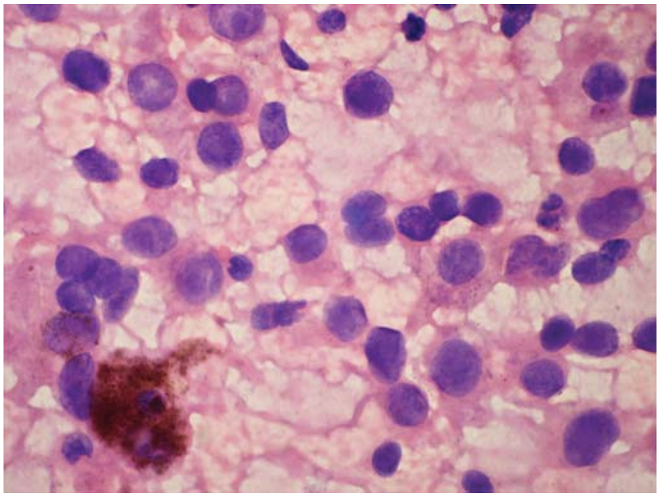

Fig. 30.29: Dispersed population of pleomorphic cells with eosinophilic cytoplasm, eccentric dark nuclei, prominent nucleoli and intracytoplasmic melanin pigment in some cells (H and E, 100X)

Metastasis

Lung metastases develop in upto 50% of all patients dying of cancer. The most common sources of lung metastases are breast, colon, pancreas, stomach, melanoma (Fig. 30.29), kidney (Fig. 30.30), germ cell tumors[85] and sarcomas (Fig. 30.31), however almost any malignant tumor can metastasize to the lung.

Usually the metastases are multiple and described as cannon – ball deposits. Both lung fields are usually involved by well delineated, multiple rapidly growing masses. Sometimes there are military nodules. Rarely it

may present as solitary nodule and may be mistaken for a primary tumor of lung. There are no reliable cytomorphological features that can distinguish primary from metastatic adenocarcinoma.[86] The cytology of a few metastatic lesions is fairly characteristic, e.g. in malignant melanoma and renal cell carcinoma.

Finally, a clear distinction between Non-Small Cell Lung Cancer (NSCLC), including subgroups and small cell lung cancer, and between primary lung cancer and metastases has therapeutic impact, but the distinction may be difficult at times on smears. In case additional smears are not available, a Cytoscrape (CS) technique can be used on virtually any smear to produce material useful for ancillary methods, including immunohistochemistry.[83,88] The CS technique improves the diagnostic information from FNA in a clinically relevant way. Immunochemistry of primary and metastatic tumors of lung is shown in Table 30.2.

Bronchoscopy

R Narasimhan, AR Gayathri

INTRODUCTION

Endoscopic visualization of the tracheobronchial tree has evolved tremendously from the initial rigid technique originally described by Gustav Killian (Fig. 31.1) in 1867,[1] when an aspirated pork bone was removed from the right main bronchus, to the path breaking invention of the flexible fibreoptic bronchoscope by Professor Ikeda, in the 1960s. Over the subsequent years, newer technologies have been developed and introduced, such as the color video camera by Ikeda and Ono in 1971, bronchoalveolar lavage (BAL) by Reynolds in 1974, video endoscope by Ikeda in 1987, stents by Dumon in 1989 and Endobronchial Ultrasound (EBUS) by Becker in 1999. The bronchoscopic practice is now widespread in India.[2] More interventional procedures are being done for both diagnostic and therapeutic purposes.

Fig. 31.1: Gustav Killian

TYPES OF BRONCHOSCOPY

Rigid Bronchoscopy

The procedure is performed under general anesthesia in the supine position with hyperextended neck, using a rigid bronchoscope (usually a ventilating bronchoscope), visualization is made better with the use of various telescopes and circumferential illumination (Fig. 31.2). Once the preliminary examination is done, the various diagnostic and therapeutic interventions (e.g. stent insertion, laser ablation, dilatation, foreign body removal) can be carried out.[3] The introduction of Charge Coupled Device (CCD) cameras, help in the transmission of images on to the monitors.

Flexible Fiberoptic Bronchoscopy

The flexible fiberoptic bronchoscopy has the advantage over the rigid bronchoscopy technique because it is easy

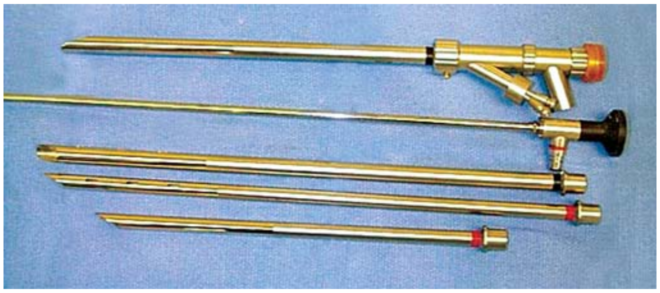

Fig. 31.2: Rigid bronchoscope

TABLE 31.1: Lignocaine content in various formulations

	Each ml of 2% Lidocaine	*Each ml of 4% Lidocaine*	*Xylocaine Viscous*	*Lidocaine Topical Aerosol 15% -Each actuation*
Lidocaine hydrochloride IP	21.3 mg	42.7 mg	21.3 mg	7.5 mg

to manipulate, simple to use, does not require general anesthesia and can be done as an outdoor procedure. Various sizes of bronchoscopes are available, which include the ultrathin bronchoscope (for the visualization of neonatal and smaller airways), pediatric bronchoscopes (2.8 mm outer diameter and 1.2 mm working channel), adult bronchoscopes (outer diameters ranging from 4.9 to 6.0 mm and channel sizes of at least 2.0 mm) and therapeutic bronchoscopes (outer diameter 6.0 mm and working channel of 2.8 mm). The video bronchoscope helps in the better visualization of lesions and data storage.

PATIENT PREPARATION AND ANESTHESIA

General and systemic examination of the patient is mandatory. Any medical condition especially cardiac or pulmonary should be identified and appropriate measures should be taken. There are varying opinions with regard to the use of sedation and premedication, prior to the procedure. In our series of patients undergoing Transbronchial Lung Biopsy (TBLB), there was no administration of either premedication or sedation, the patient comfort and cooperation for the procedure were found to be excellent.[4] Several bronchoscopists favor the use of sedation for routine bronchocopies.[5-7] With more interventional procedures being performed the world over, short-acting benzodiazepines (e.g. midazolam) and fentanyl are commonly used. The performance of an effective bronchoscopy requires the use of appropriate local anesthetics. Either two or four percent lidocaine is used, mainly for the fast onset of action, wide safety margin and the long duration of action. There is a word of caution with regard to the toxicity due to the amount of local anesthetic used, in view of a high systemic absorption of local anesthetic agent from the nasal passages and tracheobronchial tree because of the high vascularity of those regions. It is therefore essential to know the amount of lignocaine of the formulation used (Table 31.1), so as not to exceed the recommended maximum single dose of lidocaine (4.0 mg/kg).

DIAGNOSTIC BRONCHOSCOPY–ACCESSORIES

The working channel of the bronchoscope is designed to allow the use of various diagnostic and therapeutic accessories.

Biopsy Forceps

The alligator and the cupped forceps (Fig. 31.3) are the two principle types of blade design. Alligator forceps have a greater tissue tearing action than its cupped counterpart (Fig. 31.4). However, it is the cupped forceps, which obtains the larger sample size. Despite these facts, neither type of forceps has been shown to have a greater diagnostic accuracy than the other.[5] A forceps with a needle (Fig. 31.5) helps to prevent slippage and allows for the performance of tangential biopsies.

Bronchial Brushes

The bronchial brush consists of a central rigid wire surrounded at the tip by brushes, only 0.001 m of specimen is collected during bronchial brushings. The material has to be immediately transferred on to a slide (for cytology sampling) and either sprayed with a fixative or immersed in a slide container of 95% absolute ethyl alcohol. For microbiological analysis, the brush has to be agitated in 5–10 ml of sterile saline.The yield of the bronchoscopic brushing procedure increases with the proper method, collection and processing of the samples. It has also been found to be a superior technique in comparison to BAL in the diagnosis and morphological typing of lung cancer.[6]

Transbronchial Needles for Aspiration and Biopsy (TBNA)

TBNA is a minimally invasive, nonsurgical technique by which the diagnosis and staging of bronchogenic carcinoma can be done by sampling the mediastinal lymph nodes. In addition, it is useful for accessing peripheral lesions, submucosal and endobronchial lesions, as well as for the sampling of intrathoracic lymph nodes.[7] There are two types of needles available—the cytology needle and the histology needle. Four insertion

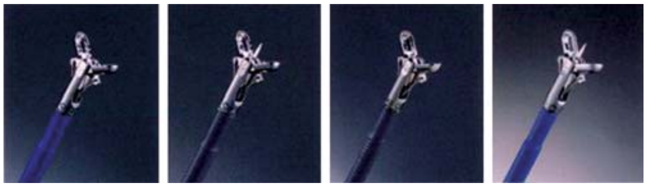

Fig. 31.3: Types of biopsy forceps

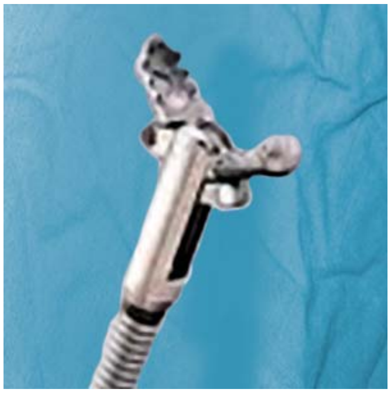

Fig. 31.4: Alligator forceps

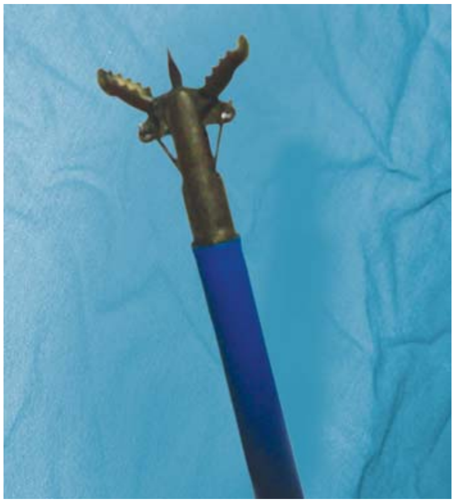

Fig. 31.5: Needle forceps

techniques have been described as follows:[8] (i) the jabbing technique, (ii) the piggyback method, (iii) hub-against-the-wall method, and (iv) the cough method. The major complication of TBNA is the perforation of the working channel of the bronchoscope. This can be avoided by careful attention to technique and needle position.

- Tracheal stenosis and strictures
- Inhalational Injury

Catheters and Balloons

Selective, protected catheters are available to collect uncontaminated specimens from the bronchial tree. The balloons available are either double lumened or low-pressure balloon catheters.

INDICATIONS FOR DIAGNOSTIC BRONCHOSCOPY

Bronchoscopy is one of the most important investigation for the diagnosis of a large number of clinical conditions and their evaluation (Table 31.2).

Assessment of Airway Anatomy

The bronchoscopic assessment of the airways begins with the visualization of the upper airways and with special reference to the vocal cords (Fig. 31.6), their appearance and mobility. The inspection of the lower airways is done

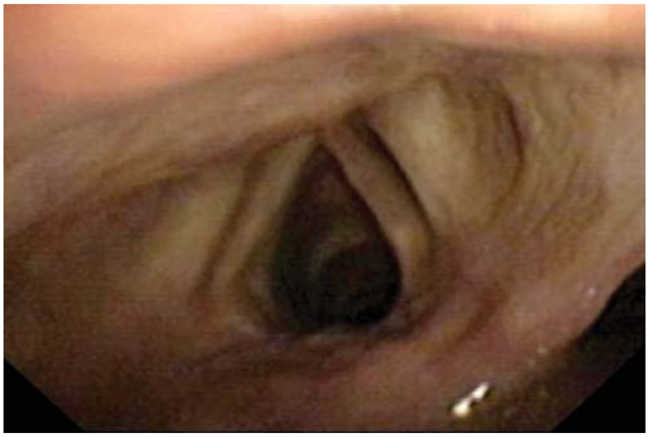

Fig. 31.6: Vocal cords

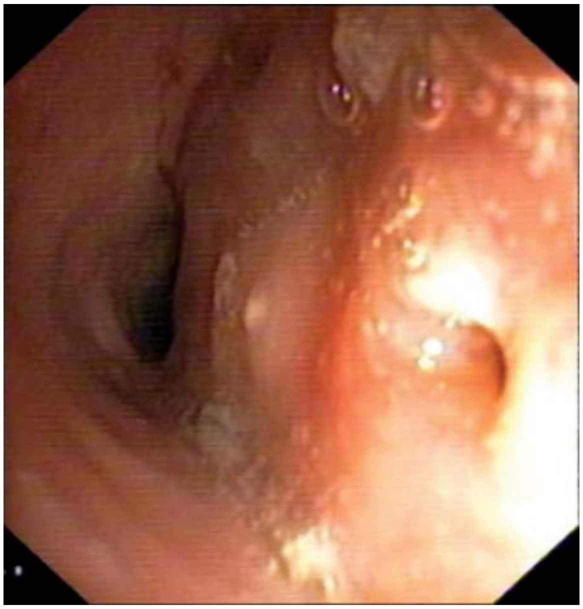

Fig. 31.7: Fistula between left main bronchus and esophagus

with specific regard to their normal anatomy, anatomical variations and pathological involvement. Specific inspection of the airway lumen can be done during inspiratory and expiratory movements. Congenital, post-traumatic, postsurgical and/or pathological disruptions in the integrity of the bronchial lumen can be visualized, e.g. bronchoesophageal fistula (Fig. 31.7).

Assessment of Tracheobronchial Mucosa

The normal mucosa of the tracheobronchial tree is pale-pink (Fig. 31.8). The presence of changes like hypervascularity (Fig. 31.9), ulcerations and granulation tissue point towards the pathological involvement. The use of photosensitizers have been used for cancer detection. The Laser Imaging Fluorescence Endoscope (LIFE), which is used in auto fluorescence bronchoscopy, generates images which are about 30,000 more times powerful than images taken with usual endoscopic cameras, by which the detection and subsequent biopsy of lesions leads to the early diagnosis of dysplasia and carcinoma *in situ*. Optical Coherence Tomography (OCT), a technique

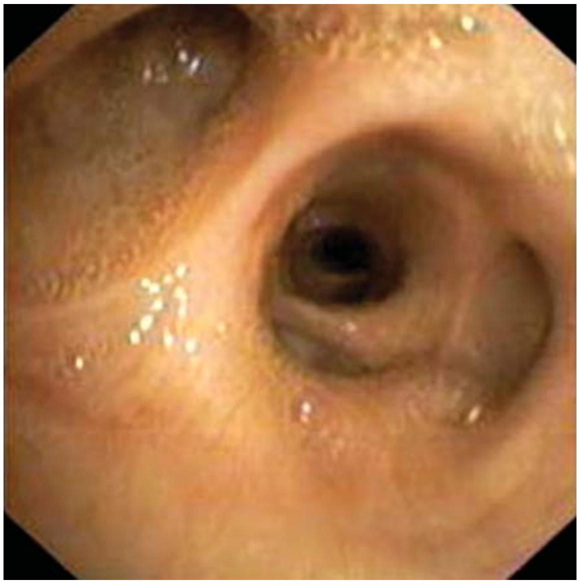

Fig. 31.8: Normal bronchial mucosa

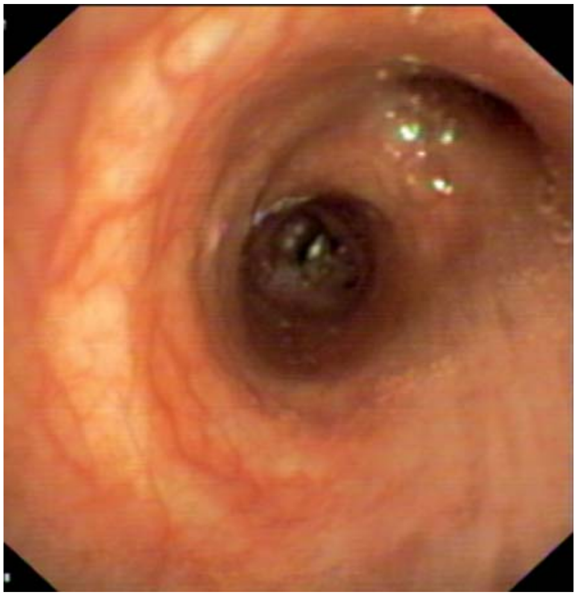

Fig. 31.9: Hypervascularity of bronchial mucosa

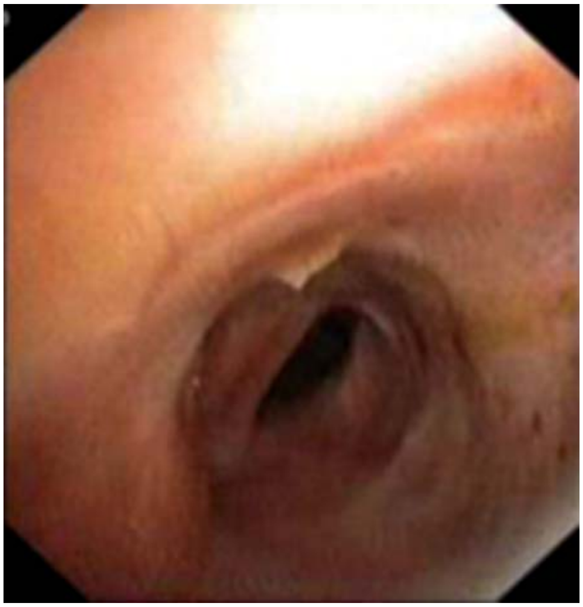

Fig. 31.10: Tracheal stenosis of lower one-third of trachea

similar to ultrasound imaging, uses infrared rather than acoustic waves.

Evaluation of Cough

Bronchoscopy is one of the recommended investigations in evaluation of patients with chronic cough especially when there is a change in the character of the cough and with an association of smoking.

Evaluation of Wheezing

Lesions like foreign bodies, tracheomalacia, vascular abnormalities, tracheal stenosis (Fig. 31.10), extrinsic or intrinsic tracheal obstructions due to mass lesions may present clinically with wheeze and may require further evaluation by bronchoscopy.

Evaluation of Stridor

Stridor is a life threatening sign of upper airway obstruction. Prior to the evaluation of likely causes (in adults), such as infections, Wegener's granulomatosis, bilateral vocal cord paralysis, tracheal tumors, tracheal compression due to mediastinal and esophageal lesions, the bronchoscopist must ensure that adequate facilities are available for emergency intubation and tracheotomy, if required.

Evaluation of the Hoarseness of Voice

It has been found that 36% of vocal cord paralysis were due to neoplastic diseases of which, 55% were from lung cancer.[9] Left hilar lesions, which may contribute to left recurrent laryngeal nerve paralysis may be sampled by TBNA.

Evaluation of Inhalational Injury

Inhalational injuries may occur due to smoke inhalation, toxin exposure or thermal injury due to steam or superheated air. Bronchoscopy is done for the initial assessment of inflammation, mucosal edema, ulceration and swelling of the laryngeal airway. It can also be used for fibreoptic intubation.

Evaluation of Hemoptysis

Bronchoscopy in the evaluation of hemoptysis helps in the identification of the location and source of bleeding. Early bronchoscopy (within 48 hours) has a greater diagnostic yield than late bronchoscopy, but an overall impact of timing on the patient management has not been found.[10] Though the rigid bronchoscope has better control of the airways and greater suction capacity, the flexible fibreoptic bronchoscope makes visualization of the smaller airways possible.

Evaluation of Superior Vena Cava Syndrome (SVCS)

TBNA of the mediastinal masses or lymph nodes causing SVCS can be done. Diagnosis can be established by bronchoscopic biopsy in about 60 to 70 % of cases.[11]

Evaluation of Peribronchial Structures

The changes, pathological or developmental, of the mediastinal structures and their effects on the tracheobronchial tree can be appreciated through bronchoscopy (Fig. 31.11). Procedures like TBNA and TBNB can be done to sample the mediastinal lymph nodes. Diagnosis and staging of lung cancer is an important indication of TBNA. The use of Rapid Onsite Evaluation (ROSE) of TBNA samples, where a cytopathologist is present in or near the bronchoscopy suite, ensures that the material is prepared in the best possible manner, with improvement in yield, and reduction in the number of inadequate specimens. It also avoids the need for further sampling, if the samples are satisfactory. Use of methods like CT fluoroscopy, EBUS and electromagnetic guidance, increase the yield of TBNA. Newer generation EBUS bronchoscopes allow for concurrent lymph node visualization and performance of TBNA.

Evaluation of Interstitial Lung Disease

Procedures like BAL have been found to be useful in studying the cells causing inflammatory response in

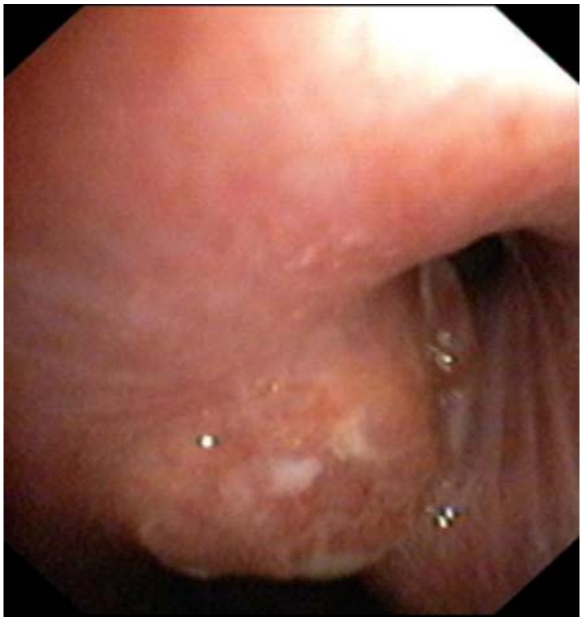

Fig. 31.11: Right hilar lymph node eroding into bronchial lumen

Idiopathic Pulmonary Fibrosis (IPF). Use of BAL and Bronchoscopic Lung Biopsy (BLB) have increased the diagnostic yield in diffuse parenchymal conditions such as sarcoidosis, histiocytosis X and lymphangitis carcinomatosa.

Evaluation of Infections

Bronchoscopy with BAL is a safe method of sampling the lower respiratory tract secretions. Bronchoscopy is more likely to have a better yield if the radiological infiltrates have been present for more than 30 days, are multilobar or segmental and if the patient is less than 55 years of age.[12]

Evaluation of Lobar Collapse

The yield of diagnostic bronchoscopy is highest, when lobar collapse is being investigated, up to 65% of patients undergoing bronchoscopy for lobar collapse had endobronchial masses.[13]

Evaluation of Pleural Effusions

Presence of hemoptysis, cough, a parenchymal lesion in addition to the pleural effusion, increase the yield of bronchoscopy in pleural effusion.

Evaluation of Chest Trauma

In patients with both blunt and penetrating thoracic trauma, bronchoscopy is an essential tool to assess the airway damage. It is also useful for fiberoptic intubation of patients, as well as to deal with post-trauma complications like mucous plugging and aspiration.

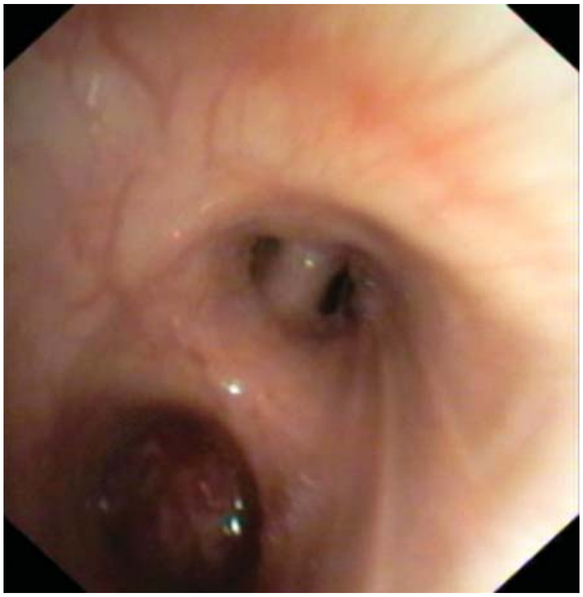

Fig. 31.12: Endobronchial mass occluding right bronchus intermedius

Evaluation of Lung Masses

Lung masses, especially those which present with endobronchial lesions (Figs 31.12 to 31.14) can be visualized through the bronchoscope and biopsied with

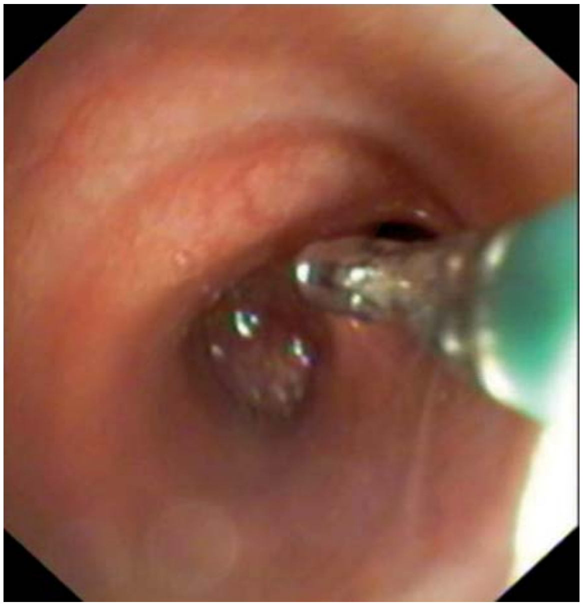

Fig. 31.13: Endobronchial mass in right bronchus intermedius being biopsied

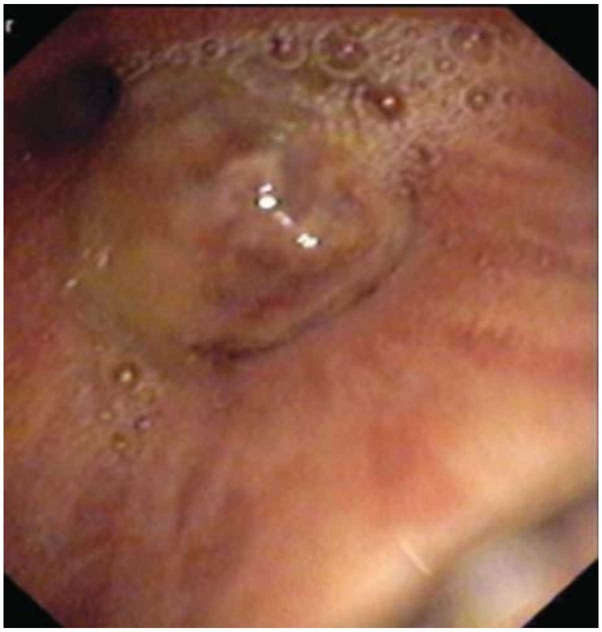

Fig. 31.14: Endobronchial mass in right lower lobe common basal segment

forceps. Three to four samples have been found to be sufficient for diagnosis.[14] The use of a combination of sampling techniques, including wash, brush, forceps and TBNA have shown to increase the yield of the diagnosis of bronchogenic carcinoma.[15]

Evaluation in Lung Transplantation

Bronchoscopy plays a valuable role in patients undergoing lung transplantation. It is useful in evaluating the presence and treatment of various airway complications like infection and stenosis, and also to differentiate between rejection and infection.

DIAGNOSTIC PROCEDURES

Bronchoscopic Lung Biopsy

Bronchoscopic lung biopsy is the technique by which biopsy of the lung parenchyma can be obtained by either the rigid or the flexible fiberoptic bronchoscope. It is also referred to as transbronchial or transbronchoscopic lung biopsy. Although found to be useful in diffuse parenchymal diseases, its use has generally declined.

The use of CT imaging in the diagnosis of diffuse lung disease has lead to a decrease in the number of bronchoscopic lung biopsies. Moreover, there are several contraindications for bronchoscopic lung biopsy[16] (Table 31.3). EBUS has shown promise in accessing peripheral pulmonary nodules, may even throw light on differences in the nodule architecture of malignant and benign lesions.

TABLE 31.3: Contraindications of bronchoscopic lung biopsy

Absolute Contraindications
1. Inability of patient to cooperate with the procedure
2. Inability to undergo general anesthesia (when required) for obtaining BLB
3. Unstable cardiovascular status
4. Acute severe asthma
5. Severe hypoxemia
6. Inadequately trained bronchoscopist or bronchoscopy team
7. Inadequate instruments for procedure performance

Relative Contraindications
1. Uncontrollable cough, during procedure
2. Untreated hemorrhagic diathesis
3. Advanced renal failure
4. Significant hypoxemia in a patient with single lung
5. Extensive bullous changes in areas to biopsied
6. Radiological suggestion of vascular malformations adjacent to areas to be biopsied

Pulmonary hypertension has been considered as a contraindication to BLB, but no significant difference was found in post BLB complications in the patients of interstitial lung disease with latent pulmonary hypertension in comparison to those patients without pulmonary hypertension.[17]

Sampling of Airway and Alveolar Constituents

The techniques used for sampling the tracheobronchial tree include the bronchial washing, bronchial brushing and BAL. The specimens can be sent for various microbiological and cytological analyses.

Bronchoalveolar Lavage

This is a relatively safe and easy procedure, which involves the instillation of measured aliquots of saline and its recovery through the bronchoscope so as to get a sample of the epithelial lining fluid of the small airways and alveoli. It is useful in the diagnosis of conditions like pulmonary alveolar proteinosis, eosinophilic granuloma and eosinophilic pneumonia.

Quantitative Microbiological Techniques

In the setting of patients with ventilator associated pneumonias, it is essential to get a sample from the bronchial tree, which is free from the contamination or

colonization of organisms. Procedures like Protected Specimen Brush (PSB) and quantitative BAL help in acquiring representative samples.

THERAPEUTIC BRONCHOSCOPY

Bronchoscopy is also employed for several therapeutic indications (Table 31.4).

Foreign Body Aspiration and Removal

Bronchoscopy finds a major role in the removal of foreign bodies. Traditionally, the rigid bronchoscope had been the instrument of choice for foreign body removal, but now the flexible fiberoptic bronchoscope is being increasingly used. It offers greater access to the periphery and can be used with ease in patients on mechanical ventilator and those who have unstable neck. The various instruments used for foreign body removal include snares, balloon catheters, retrieval baskets and grasping forceps (Fig. 31.15).

Control of Hemoptysis

Bronchoscopy is useful for both diagnosis and emergency management of hemoptysis. An instrument with a larger working channel is required, the use of rigid bronchoscopy is recommended. Various measures like instillation of iced saline solution and epinephrine, may be tried. Catheters to offer tamponade on bleeding segments, including Fogarty balloon catheter may be tried. In the event, a visible source of bleeding is seen and laser photocoagulation can be attempted.

Pulmonary Toilet

Clearing of tracheobronchial tree of secretions called toileting, is the most common application of therapeutic bronchoscopy. Bronchoscopes with large suction channel are to be used. This is commonly required in ICU practice.

Bronchoalveolar Lavage

Whole lung lavage in patients with Pulmonary Alveolar Proteinosis (PAP) has a therapeutic, as well as diagnostic role. About 50% of patients will suffice with a single treatment (Fig. 31.16), multiple lavages are required in other patients.[18]

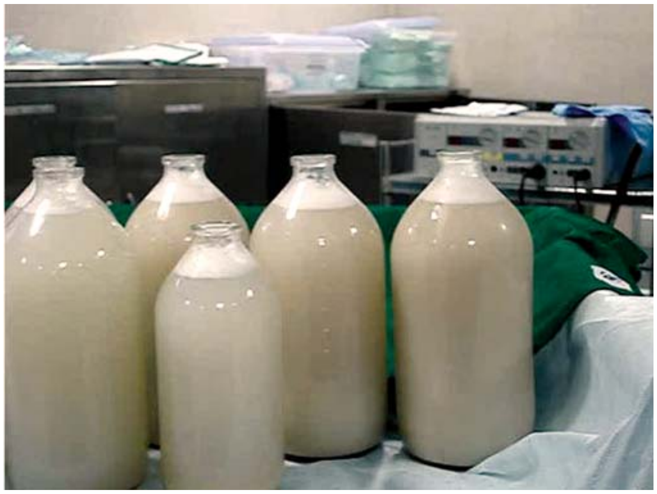

Fig. 31.16: Lavage fluid from the whole lung lavage of pulmonary alveolar proteinosis

Electrocautery and Argon Plasma Coagulation

Electrocautery can be used via the bronchoscope channel in a contact or noncontact mode. It has the advantage over laser because it requires a shorter procedure time and lesser investment for instrument overheads. Indications for electrocautery include the treatment of malignant and benign lesions, debulking of tumors and removal of granulation tissue, hemoptysis management, immediate hemostatic control and coagulation.

Cryotherapy

It is one of the modalities used for the treatment of malignant endobronchial lesions. The principle of treatment is to create the fastest possible cooling of the target tissue in order to provoke intracellular freezing. The cooling agents used are liquid nitrogen, nitrous oxide and carbon dioxide.

Laser Photoresection

The use of laser in obstructive endobronchial lesions allows the establishment of airway patency and the subsequent ventilation of the distal lung and drainage of the postobstructive pneumonia. Other lesions treated by laser photoresection include tracheal granulomas, tracheal stenosis, endobronchial amyloidosis and tracheopathia osteoplastica.

Photodynamic Therapy

Photosensitizers are used to cause tissue necrosis. The likely indications for this therapy include the treatment of early lung cancer or palliation of unresectable bronchogenic carcinoma causing tracheobronchial obstruction.

Balloon Dilatation

It is used to establish airway patency in patients with retention pneumonia, atelectasis, lung abscess or the symptomatic stenosis of tracheobronchial tree.

Tracheobronchomalacia

Tracheobronchomalacia is diagnosed by flexible bronchoscopy. The treatment of choice for diffuse involvement is the insertion of standard or bifurcated silicone tracheobronchial stents. Pneumatic stent with concomitant noninvasive ventilation is another treatment option.

Fistula Closure/Repair

Identification of fistulae beyond the reach of flexible fibreoptic bronchoscope is done by the serial insertion of occluding balloons and checking for air leak. Various sealants like gel foam, autologous blood patches, cryoprecipitate and silver nitrate can be used to close the fistula. Up to 83% of tracheoesophageal fistulas can be detected by bronchoscopy, further treatment can be planned by concomitant esophagoscopy.[19]

Stents

Stents are placed bronchoscopically, to relieve endoluminal obstruction. Both flexible and rigid bronchoscopes are used for stent placements. Patients with primary airway tumors may benefit from endoluminal stenting, if surgery is not indicated. Other tumors that occur adjacent to the airway and produce obstruction by direct invasion or extrinsic compression, may also be successfully palliated with endoluminal treatments combined with stent placement. Patients with postintubation tracheal stenosis are occasionally good candidates for airway dilation and stenting.

Endobronchial Valves (EBV)

Bronchoscopic lung volume reduction using endobronchial valves for selected patients with hyperinflated lung from heterogeneous emphysema has been attempted. The use of endobronchial valves to treat persistent pulmonary air leaks has been shown as an effective and minimally invasive procedure.[20]

ELECTRONAVIGATION BRONCHOSCOPY

It is a procedure, which incorporates the patient's CT chest images into a special computer software program, to mark the exact site of lesion by placing electronic markers. It is done for virtual guidance for the bronchoscopist to sample the specific lesion by biopsy, brush or TBNA. The procedure is done under conscious sedation, with the patient lying on a low frequency electromagnetic bed.

SAFETY FACTORS IN BRONCHOSCOPY

Bronchoscopy is a technique, which requires expertise and training. Knowledge of airway anatomy is essential. Adequate equipment, trained personnel and means of handling complications, which may arise are essential.

TABLE 31.5: Complications of bronchoscopy

Complications related to anesthesia
- Hypersensitivity to local anesthetic agents

Oxygen Desaturation
Fever
Infection
Airway Obstruction
Airway Perforation
Pneumothorax
Hemorrhage
Air Embolism

Standard safety precautions when handling the equipment and performance of procedures are essential.

COMPLICATIONS OF BRONCHOSCOPY

Bronchoscopy has a potential of hazards of anesthesia, as well as of the procedure and associated interventions (Table 31.5). The complications are more likely if the basic prerequisites like patient selection and preparation are not appropriate.

Anesthesia-Related Complications

The importance of having a limit on the amount of local anesthetic, which is used has been mentioned earlier. It is essential to remember that oxygen desaturation may occur during the procedure, especially when done under conscious sedation or general anesthesia. Significant desaturation occurs during BAL. An essential prerequisite therefore, is the administration of supplemental oxygen.

Fever and Infection

The occurrence of transient fever, after bronchoscopy especially after the performance of BAL has been noted. The use of prophylactic antibiotic prior to procedure, as recommended by the American Heart Association, is for patients with a predisposition to endocarditis and those with valvular heart problems. Prohylactic antibiotics are not required prior to flexible bronchoscopy.

Airway Perforation and Obstruction

Various airway complications, including burns, perforation and airway obstruction, may occasionally occur when lasers, stents or valves are used, and when the procedures are inappropriately performed.

Pneumothorax

The incidence of pneumothorax following a transbronchial biopsy is about four percent. The risk increases when the patient is immunocompromised with associated pneumocystis infection, when the patient has multiple bullae in the lungs and when the patient is on a mechanical ventilator.

Hemorrhage

Its occurrence due to the procedure itself, can be avoided by proper selection and evaluation. As per standard recommendations, bronchoscopy should not be performed if the platelet count is less than 50,000/mm^3. Other interventional procedures, including TBLB, laser and stents should be done only if the platelet counts are more than 75,000/mm^3.

Air Embolism

This a serious and fatal complication, which rarely occurs, especially after laser photoresection.

Inspite of the likelihood of several complications, which have been enumerated, the procedure of bronchoscopy is generally safe and risk free. It is however important that it is done by trained personnel with ready availability of backup facilities to handle any complication.

Interventional Bronchoscopy

Praveen N Mathur, FD Sheski

DEFINITION OF INTERVENTIONAL PULMONOLOGY

Interventional pulmonology is a very young and rapidly growing field within pulmonary medicine that focuses on the use of advanced bronchoscopic and pleuroscopy techniques. This was first defined in 1995[1] and subsequently by the ERS/ATS guidelines.[2] Interventional pulmonology can be defined as "the art and science of medicine as related to the performance of diagnostic and invasive therapeutic procedures that require additional training and expertise beyond that required in a standard pulmonary medicine training program." Disease processes encompassed within this discipline include complex airway management problems, benign and malignant central airway obstruction, pleural diseases, and pulmonary vascular procedures. Diagnostic and therapeutic procedures pertaining to these areas include, but are not limited to, rigid bronchoscopy, transbronchial needle aspiration, autofluorescence bronchoscopy, endobronchial ultrasound, transthoracic needle aspiration and biopsy, laser bronchoscopy, endobronchial electrosurgery, argon plasma coagulation, cryotherapy, airway stent insertion, balloon bronchoplasty and dilatation techniques, endobronchial radiation (brachytherapy), photodynamic therapy, percutaneous dilatational tracheotomy, transtracheal oxygen catheter insertion, medical thoracoscopy, and imaging-guided thoracic interventions.[1,2]

Although this definition was established in 1995, there has been a surge of new procedures that now can be performed with a bronchoscope. This area continues to thrive with new innovation and venture capital. Some of them are: Endoscopic lung volume reduction for advanced emphysema, bronchothermoplasty for asthma, and newer spectroscopic imaging techniques. As we learned to perform these procedures safely we have not defined the value of these procedures in controlled trials.

In this chapter, only the interventional bronchoscopy is addressed.

Rigid Bronchoscopy

Bronchoscopy was first performed with a rigid bronchoscope in 1897 by Gustav Killian to remove a pork bone impacted in the airway of a farmer. Killian used a Mikulicz-Rosenheim rigid esophagoscope.[3] Killian continued to use rigid metal tubes in cadavers, he subsequently described the extraction of foreign bodies from the airway. Chevalier Jackson in Philadelphia was responsible for the development of rigid bronchoscopy in the United States. He improved and developed the modern rigid bronchoscope.[4] The development of the flexible bronchoscope leads to the decrease of the use of rigid bronchoscope. However, rigid bronchoscopy has regained usefulness due to the increasing use of interventional bronchoscopy.[5]

The rigid bronchoscope, also known as the open tube bronchoscope, is a nonflexible, straight, and hollow metallic tube made of stainless steel. The tube comes in various external diameters, which vary from 2 to 14 mm. They have the same diameter from the proximal to the distal ends, but most have a beveled tip to facilitate lifting of the epiglottis during intubation and also to core out an endobronchial lesion.

Telescopes were made with 0 degree and multitude of angles, allowing the visualization of upper and lower lobe bronchi. Many of the angled telescopes are not used as the fiberoptic bronchoscope, but are used through the rigid tube. Light sources using xenon or halogen lamps are currently used. Video cameras can be easily connected to the eyepiece of a rigid telescope. Accessory instruments often used during rigid bronchoscopy include biopsy forceps, suction tubing, and specific forceps that may become necessary for removal of foreign-body. This procedure is performed under general anesthesia. The teeth must be protected, a rolled blanket placed between the shoulder blades, which enables the upper trachea to move forward. Anesthesia could be intravenous; if inhaled anesthetic gases are to be used, it is necessary to pack with gauge the nose and mouth to avoid gas leakage. Ventilator support is provided using assisted spontaneous ventilation or closed-circuit positive pressure ventilation.

Several techniques are used for the intubation of the rigid bronchoscope: a. direct intubation is the method of choice for intubation; b. intubation with the help laryngoscope, or c. intubation alongside a small endobronchial tube.

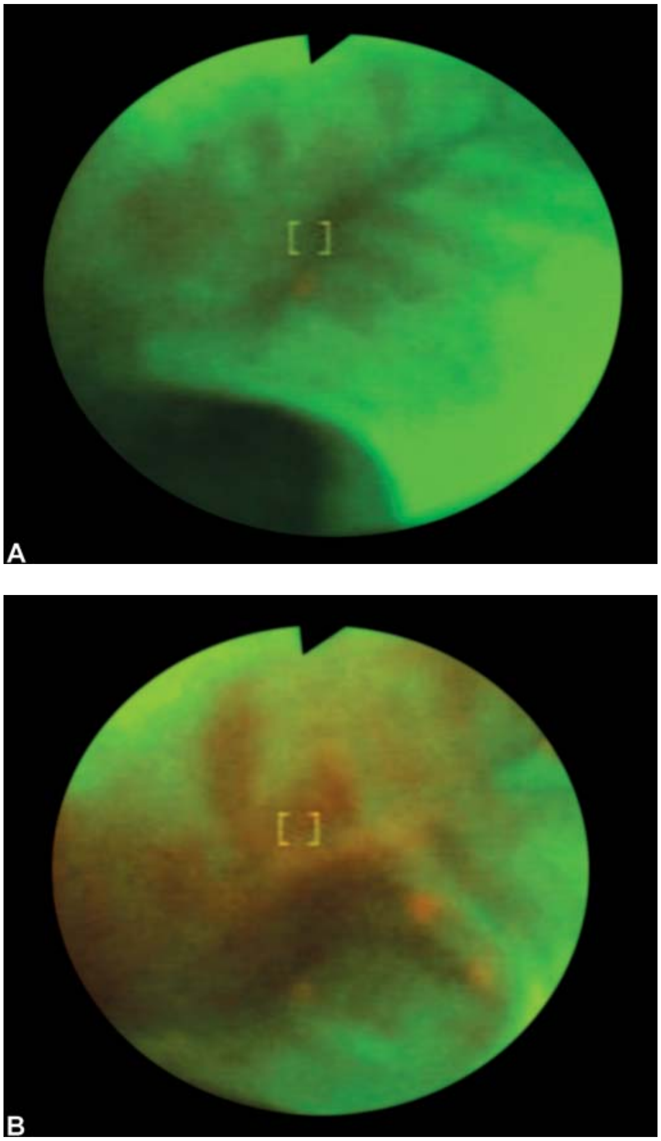
Complications are related to poor insertion technique such as trauma (to gums, teeth, lip) and laryngeal swelling.

The rigid bronchoscope is used for interventions, such as endoscopic resection of endobronchial masses with laser, electrocautery argon plasma coagulation or cryotherapy; placement of silicone stents, and finally for the removal of foreign bodies.

ADVANCED IMAGING BRONCHOSCOPY

Fluorescence Bronchoscopy

Lung cancer progresses through several stages, including metaplasia, dysplasia, carcinoma *in situ*, microinvasive carcinoma, and invasive carcinoma.[6] In order to identify this abnormal mucosa, a variety of techniques have been used. When a suitable wavelength is used to excite tissue to fluoresce, infiltrating tumor will alter tissue fluorescence. This difference in fluorescence is used to help in detecting abnormal mucosa in the airways. Photosensitizing fluorescent compounds were used to increase the intensity of the fluorescence, but this approach has been limited by skin phototoxicity.[7-10] Advances in image processing have improved the detection of subtle differences in fluorescence. Carcinoma *in situ* and microinvasive carcinoma exhibit a weaker red fluorescence and slightly weaker green fluorescence for normal tissues, when illuminated by light with a wavelength of 380 to 440 nm (Figs 32.1A and B). Several reasons suggested as this phenomenon are not well understood. This may be due to increased epithelial thickness, increased blood flow, and/or a reduced concentration of fluorophores in abnormal tissue.[11,12]



Figs 32.1A and B: Carcinoma *in situ* and microinvasive carcinoma exhibit a weaker red fluorescence (A) and slightly weaker green fluorescence for normal tissues (B)

The first fluorescence bronchoscopy system that was commercially available was the Light-induced fluorescence endoscopy (LIFE) device (Xillix Technologies Corporation, Vancouver, Canada).[13,14] This device used blue light from a helium-cadmium laser and collected fluorescence images via its imaging bundles. The red and green wavelengths reflected by the tissues were filtered and amplified by cameras. A variety of different manufacturers has used similar technology and also displayed numerically to provide quantification. A variety of different color schemes has been used by different manufacturers. Fluorescence and white light bronchoscopy is performed during the same session.

Most of the studies have performed conventional White light bronchoscopy (WLB), followed by Autofluorescence (AF) Bronchoscopy. Biopsies were taken from abnormal and normal areas. AF bronchoscopy was better at detecting airway lesions than WLF,[15] but was also more likely to give false positive results.[16] In one study, 95 out of 285 (33%) biopsies have taken from areas with abnormal fluorescence contained abnormal histology, a positive predictive value of only 33%.[17] There are no accepted indications for AF. It has a role in radiological occult sputum atypia, surveillance in patient with known carcinoma *in situ* or high grade dysplasia. AF bronchoscopy may be helpful in the evaluation of patients with invasive carcinoma who are being considered for curative endobronchial or surgical treatment.

Not all high grade lesions are premalignant and progression has been confirmed histological in fewer than 100 patients.[15,18] In addition, one study found that such progression probably occurred in 1 out of 3 patients; the rest regressed to normal.[18] The natural history is not well understood as there are difficulties due to the lack of agreement among pathologists.

High-Magnification Bronchoscopy

Neovascularization or increased mucosal microvascular growth[19,20] is a hallmark of early lung cancer. High-magnification bronchoscopy (HMB) uses this principal to identify abnormal mucosa. This system can provide information about the bronchial mucosa with a maximum magnification of 110 times. Such increased vascularity in the bronchial mucosa is also seen in asthma and chronic bronchitis. Areas of complex networks of tortuous vessels in the bronchial mucosa that are detected using HMB at sites of abnormal fluorescence may enable discrimination between bronchitis and dysplasia. The sensitivity and specificity of HMB is 70% and 90% respectively.[19] This promising work has not been duplicated at any other institution.

Narrowband Imaging

This neovascularization or increased mucosal microvascular growth can be observed, if a new narrowband filter is used instead of the conventional red/green/blue broadband filter. This narrowband imaging (NBI) technique uses a 415 nm blue light, which is absorbed by hemoglobin contained in the capillary network on the mucosal surface and a 540 nm green light that is absorbed by blood vessels located a bit deeper below the capillary layer.[21] NBI was shown to increase the rate of detection of dysplasia or malignancy by 23% when compared to WLB,[22] however when combined with AF bronchoscopy, there is no increase yield.[23]

Optical Coherence Tomography (OCT)

This is also a noninvasive technique for endoscopic imaging of *in vivo* tissue structure. Optical coherence tomography resembles ultrasound, but uses light rather than acoustic waves. On ultrasound, the resolution of the quality of image is often obscured due the presence of air, OCT overcomes this problem. Velocity of light is 200,000 times greater than the velocity of sound, thus the resolution is much improved, but the depth is only up to 2 mm.[24,25] The procedure can be performed with standard bronchoscopy. OCT can localize preneoplastic changes in the bronchial epithelium once identified by AF bronchoscopy. Carcinoma *in situ* (CIS) and invasive carcinoma can be identified from normal bronchial epithelium.[26,27] It may have role in understanding the airway remodeling in Chronic Obstructive Pulmonary Disease (COPD) and asthma as the details of airway can be visualized up to 2 mm.[28]

Confocal Endoscopy

Optical technological advances for endoscopic imaging continue to proliferate, confocal endoscopy endomicroscopy is another one such advancement. This has the capabilities for submicrometer-level resolution imaging, but has further limitations in the depth of penetration (approximately 0.5 mm compared with approximately 2 to 3 mm with OCT).[29] It is envisioned that sometime soon in future, the optical technologies will provide a window to intracellular structures *in vivo*, replacing the traditional *in vitro* analyses of cellular components using conventional tissue biopsy specimens.

ADVANCED BIOPSY TECHNIQUES

Transbronchial Needle Aspiration (TBNA)

Needle aspiration of mediastinal lymph nodes was initially recognized in 1949, its application via flexible bronchoscopy was later described in 1981.[30,31] However, the TBNA has been utilized in the diagnosis of endobronchial lesions, peripheral nodules, and mediastinal abnormalities.[32-34] The most common application of TBNA is the diagnosis and staging of lung cancer.

Technique

In order to perform optimal TBNA; a computed tomography of the chest is performed with contrast prior to TBNA. The relationship of the tracheobronchial tree to the lymph nodes and blood vessels are essential to know. The needle must reach the core of the lymph node to get optimal biopsy while avoiding nearby vascular structures. TBNA of lymph nodes in the subcarinal and right paratracheal regions detects metastasis with a higher sensitivity than TBNA of left paratracheal lymph nodes.[35]

When someone is going to perform TBNA, he first must learn and understand the mediastinal anatomy. As the bronchoscope is passed to the right of the distal third of the trachea the superior vena cava and the azygos vein is found. Directly anterior to the trachea, above the level of the primary carina is the innominate artery and the aortic arch. They cross the origin of the left main stem bronchus and then lie anterior and to the left of the distal third of the trachea, making an easily recognizable pulsatile imprint.[36] The main pulmonary artery divides into the right and left branches within the concavity of the aortic arch. The left pulmonary artery runs anterosuperiorly, in close approximation (within 3 to 5 mm) to the left main stem bronchus, while the right pulmonary artery lies anterior to the right mainstem bronchus and the origin of the upper lobe bronchus. The esophagus lies in close approximation (within 2 to 3 mm) to the posterior wall of the trachea and the left mainstem bronchus.[36]

Only the retractable needles should be used, as the damage to working channel is common and costly, the commonly used size is 22 Gauge (G) needle to obtain cytology. There is a larger 19 G needle that has been used for histology; however, it is cumbersome system with poor performance record. During insertion of the catheter, the flexible bronchoscope should be kept as straight as possible, with its distal tip in the neutral position in order to prevent damage to the working channel. The tip of the needle should be kept within the metal hub during its passage through the working channel.[37] The catheter should be retracted, and the tip of the needle kept in view distal to that of the fiberoptic bronchoscope. The bronchoscope is then advanced as a single unit to the target area, and the tip of the needle is anchored in the intercartilaginous space so as to penetrate the airway wall. The needle should be inserted with the metal hub against the tracheobronchial wall. When the needle is inserted, suction is applied at the proximal side port using a 60 ml syringe. The catheter is then agitated to and fro to obtain cytology with continuous suction. The needle is withdrawn from the target site after releasing suction.

The specimen for cytology is prepared by using air from a 60 ml empty syringe to spray the specimen onto the slide, smearing it using another slide, and immediately placing it in a 95% alcohol solution. If Rapid On-Site Evaluation (ROSE) service is available, then feedback from the cytologist is extremely helpful and reduces the number of punctures.[38] The cytopathologist reviewing the sample for adequacy has been demonstrated to increase diagnostic yield.[38] A trained assistant is essential for the success of TBNA and proper tissue handling.

Complications following TBNA are uncommon if appropriate precautions are taken and the proper technique is employed. Damage to the working channel of the bronchoscope is most common. There are no firm recommendations on antibiotic prophylaxis. Oozing of a minimal amount of blood from the puncture site may be encountered; infrequent complications include pneumothorax, pneumomediastinum and hemomediastinum.

Outcomes

A meta-analysis of 42 studies examining the accuracy of CT in detecting mediastinal nodes infiltrated with malignancy reported sensitivity and specificity of 79% and 78% respectively.[39] The sensitivity and specificity of TBNA for the diagnosis of non-small cell lung cancer was 39% and 99% respectively in other large meta-analysis of 113 studies.[40] TBNA establishes the diagnosis and provides staging information in a single procedure. A positive N2 or N3 lymph nodes for non-small cell lung cancer avoids surgical intervention. Positron Emission Tomography (PET) helps in defining, which lymph nodes should be sampled.

The utility of TBNA in the diagnosis of lymphoma has been limited, this usually requires larger samples of nodal tissue. Several reports have confirmed an increase in the diagnostic yield when both transbronchial lung biopsies and TBNA are performed in patients with suspected sarcoidosis.[41,42]

Endobronchial Ultrasound (EBUS)

This bronchoscopic technique uses ultrasound to visualize structures of the mediastinum adjacent to the airway wall to perform TBNA. EBUS can be used to guide bronchoscopic sampling of mediastinal lymph nodes, hilar lymph nodes, or peripheral pulmonary nodules.[43,44] EBUS is different than EUS. While both visualize and guide the sampling of mediastinal lymph nodes, EBUS is performed during bronchoscopy and EUS is performed during upper endoscopy.

Techniques

Various techniques for endobronchial ultrasound include the following:

i. *RP-EBUS:* Radial Probe EBUS (RP-EBUS) provides 360° images of the airway wall and surrounding structures, and visualize the layers of the airway wall. RP-EBUS is performed by placing the bronchoscope tip in the area of interest, inserting the radial ultrasound probe through the working channel and inflating its balloon sheath with water. Twenty MHz or Thirty MHz miniature radial probes are available, which provide a depth of penetration of 5 mm. An ultra-miniature radial probe can be extended into subsegmental bronchi allowing peripheral pulmonary nodules to be visualized. The probe and guide sheath are advanced through the working channel of the bronchoscope until the nodule is visualized, radial probe is removed, leaving the guide sheath in position. Biopsy forceps or a bronchial brush is then inserted through the guide sheath and the nodule to be biopsied. When RP-EBUS is used for TBNA the radial probe is removed from the working channel before the TBNA can be inserted, thus it is not performed in real time.

ii. *CP-EBUS:* Convex Probe EBUS (CP-EBUS) gives a view, which is parallel to the shaft of the bronchoscope. This allows real-time TBNA, color flow Doppler will help identify vascular and cystic structures. A 7.5 MHz convex ultrasound probe is a part of the bronchoscope at its tip. The ultrasound image and conventional bronchoscopy image can be displayed on the same monitor, but two separate monitors are preferred. A transbronchial needle system containing a 22 G retractable sharp beveled needle with an internal sheath is inserted through the working channel, just proximal to the ultrasound probe. Once the catheter emerges from the bronchoscope, the needle is advanced from the catheter and locked into position. It is then pushed through the inter cartilage space and into the target lymph node under ultrasound visualization (Figs 32.2A to C). Suction is applied with syringe and the catheter is slowly agitated. The needle is pulled into the flexible catheter after suction is released. The specimen is prepared in a similar manner as TBNA.

Outcomes

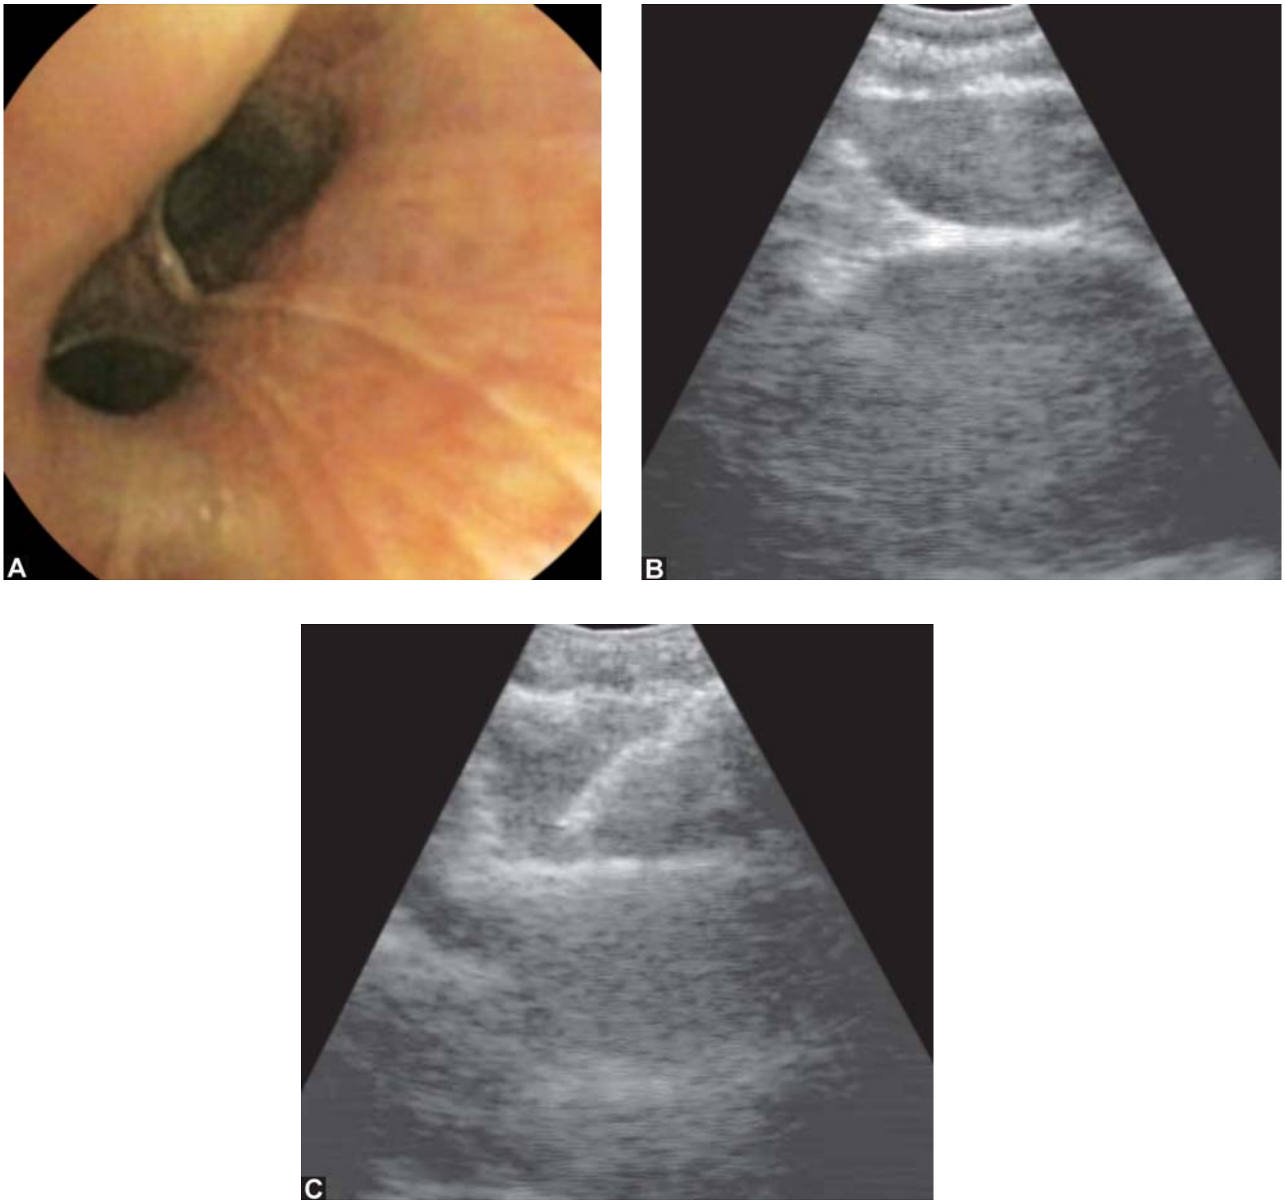
Various outcomes of endobronchial ultrasound include the following:

i. *Mediastinal lesions:* EBUS is employed once an enlarged mediastinal lymph node is identified by CT scan or is metabolically active on a PET.[45] In an initial clinical trial, RP-EBUS was used in suspected lung cancer.[46] Patients with lymphadenopathy were randomized to RP-EBUS and TBNA. Positive result was defined as yielded lymphocytes or a specific abnormality on cytology. In patients with lymph nodes, which were other than subcarinal, RP-EBUS-guided TBNA had an improved yield (84% vs 58%) when compared to TBNA. RP-EBUS did not add any further value when subcarinal lymph nodes were analyzed.

   CP-EBUS-guided TBNA could successfully sample mediastinal or hilar lymph nodes,[47] malignancy was detected with a sensitivity of 95% and the specificity of 100%, and diagnostic accuracy of 96%. Similar sensitivity and specificity were shown in a large meta-analysis of 11 studies.[48] When a combination of EBUS-guided TBNA and endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) is used to access mediastinum, there is a good possibility of making the entire mediastinum accessible thus decreasing the need for more invasive procedures. The combination appears to improve the diagnostic yield, when compared to either procedure alone.[49,50]

   CP-EBUS-TBNA has been used with to diagnose sarcoidosis. This has been demonstrated by a randomized study where EBUS has been shown advantageous than conventional TBNA.[51] EBUS had a sensitivity of 83% and specificity of 83%, while conventional TBNA had a sensitivity 61% and specificity of 100%. Similarly, EBUS is an effective method for diagnosing mediastinal lymphoma.[52]

   The EBUS have certain disadvantage as the bronchoscope is larger than the conventional bronchoscope with a poorer image quality. As the vision is 30° above, it is technically difficult to maneuver and requires practice. Due to its poorer



Figs 32.2A to C: Extrinsic compression (A) EBUS view of the lymph node (B) EBUS needle visible in the lymph node (C)

quality image, it should not be used for initial inspection. There is no histology needle available with EBUS, the size is the same as TBNA of 22 G.

ii. *Pulmonary nodules:* In a prospective study of 150 patients with peripheral pulmonary nodules, RP-EBUS-guided forceps biopsy using a guide sheath, was diagnostic in 77% of cases.[53] The yield was not impacted by lesion size. In comparison, prior studies when a guide sheath was not reported a diagnostic yield of up to 28% only. Other studies have similarly reported a diagnostic yield of approximately 79% when a guide sheath is used.[54] In a large randomized trial assigning patient to RP-EBUS-guided or conventional transbronchial biopsy,[55] RP-EBUS-guided transbronchial biopsy identified malignant disease with a sensitivity of 75% and accuracy 83% in nodules that were smaller than 3 cm. In contrast, conventional transbronchial biopsy identified malignant disease with a sensitivity of 31% and accuracy of 50%.

However, the yield is lower than with CT-guided percutaneous transthoracic needle aspiration. The RP-EBUS only provides an advantage if the lesion is smaller than 3 cm.

Navigational Bronchoscopy

Navigational bronchoscopy provides a virtual 3-D map to enable a physician to perform biopsy, place markers for radiation therapy or facilitate the surgeon to remove a small peripheral lesion. Bronchoscopic lung biopsy has been one of the methods to obtain tissue from a peripheral lesion. The yield for the lesion of less than 2 cm is very poor. Transthoracic needle aspiration with CT-guidance is commonly used where variable results on diagnosis and complication rates are reported. Depending on the author's intension, these variable numbers are used to either exaggerate or minimize the true impact.

Navigational systems use either an electromagnetic navigation assistance or computer assistance to identify the air columns to reach the final destination. This procedure requires several steps prior to the bronchoscopy. A CT is performed to the specification of the manufacturer. These images are transferred to laptop containing specific proprietary software and the planning is performed. Depending on the software, the virtual plan is generated. This virtual plan is placed in the navigational computer; finally bronchoscopy is performed with fluoroscopic assistance. A variety of steerable catheters can be placed in the working channel. The target is approached through an extended working channel and the navigational catheter with help of the navigation system. Once the target is reached, forceps or brushes are used to obtain tissue or fiducial markers placed.

Several studies have reported a diagnostic yield of 64 to 69%.[56,57] In a multicenter, randomized, controlled trial where EBUS, navigation system or EBUS combined with navigation system were used, the diagnostic yield was only 72%. The combined yield for EBUS with Electromagnetic Navigation Bronchoscopy (ENB) was 88%. This has not been reproduced anywhere else.[58]

The capital equipment cost is above 200,000 US dollars and disposable equipment for every case is above 1,000 US dollars, which make these systems currently prohibitive. Similarly, the EBUS systems are also in the same dollar range.

ENDOSCOPIC PALLIATIVE CARE

Begin or malignant tracheobronchial obstruction can lead to acute respiratory distress, even asphyxia and death. Endobronchial obstruction may present as an endobronchial lesion, an extraluminal obstruction or sometimes a combined lesion.

If curative resection is not possible, various endoscopic methods for palliation are available such as Neodymium-Doped Yttrium Aluminium Garnet (Nd:YAG) laser, cryotherapy, electrocautery, Argon Plasma Coagulation (APC) and photodynamic therapy. In case of extraluminal lesions, palliation is performed by balloon dilatation, stent placement, and/or external beam radiation.

These patients present with dyspnea, cough, chest discomfort, hemoptysis, stridor or localized wheeze. The history may include known cancer, aspiration of a foreign body, prior airway surgery or intubation, recurrent pneumonia, or other underlying illnesses that may involve the airways such as sarcoidosis or tuberculosis.

ND:YAG LASER

Using theories proposed on radiant energy in 1917,[59] Schawlow and Townes[60] formulated the hypothesis of laser light with the subsequent development of a ruby laser reported by Maimon in 1960.[61]

Laser technology makes use of the power of radiant energy and properties of light amplification, "laser" being an acronym for "light amplified by the stimulated emission of radiation". For the stimulated emission of light to occur, there must be an adequate population of excited electrons with the subsequent release of photons to produce the laser light. This phenomenon is termed population inversion, requires an outside energy source exciting a designated medium. Almost any solid, liquid or gas may act as a medium. Placing the substance to be excited in a chamber with mirrors at either end further facilitates population inversion. The effectiveness of laser light, as opposed to naturally occurring light, has to do with three important properties[62]—wavelength, spatial coherence and temporal coherence.

The amount of energy that is delivered to a lesion depends on the power setting of the laser expressed in watts, the distance from the laser tip to the target, and the duration of impact.[63] Light directed at a surface may also be reflected, scattered, transmitted or absorbed.[63] The depth of penetration, therefore, depends not only on the properties of the light, but also on the inherent properties of the tissue; the characteristics of the light produced also depend on the medium used.

In the CO_2 laser, the light is produced in the infrared spectrum at a wavelength of 10,600 nanometers. The CO_2

laser can be used as a precise cutting tool, with only minimal blood loss owing to a relatively shallow depth of penetration. The most widely used laser light for tracheobronchial lesions is the Nd:YAG laser, which is produced by the stimulation of an yttrium-aluminium-garnet glass, coated with neodymium. The Nd:YAG laser has a wavelength of 1,064 nanometers and is easily transmitted through pale tissues, with sizeable scatter and a potential penetration of up to 5 to 10 mm from the focal point.

The CO_2 laser therapy is most commonly used in the management of laryngeal lesions involving the area about the glottic opening. The CO_2 laser serves as an excellent scalpel since scattering is minimal; tissue vaporization is rapid with minimal damage to tissue. The Nd:YAG lasers, unlike the CO_2 laser, can cause deep tissue vasoconstriction, with a penetration depth of up to 10 mm, but has very good coagulation properties.

Indications and Contraindications (Tables 32.1 and 32.2)

Clinical contraindications are relevant in patients who may not tolerate the conscious or general anesthesia because of comorbid diseases. In addition, patients in whom atelectasis distal to the obstruction has been present for more than four to six weeks will probably not benefit from endoscopic laser resection because re-expansion of the involved lung is unlikely.

Complications

Complications of laser therapy are related to the laser equipment or instruments, the anesthesia used, and perioperative causes. However, despite the possibility of severe, often fatal complication, the overall risk is low. In one series, there were only 60 complications and 12 deaths associated with Nd:YAG laser therapy in 2,610 resection cases.[64]

TABLE 32.1: Contraindications for laser/cryotherapy/ electrocautery APC

Anatomic Contraindications
- Extrinsic obstruction without endobronchial lesion
- Lesion incursion into bordering major vascular structure (e.g. pulmonary artery) with potential for fistula formation
- Lesion incursion into bordering esophagus with potential for fistula formation
- Lesion incursion into bordering mediastinum with potential for fistula formation

Clinical Contraindications
- Candidate for surgical resection
- Unfavorable short-term prognosis without hope for the palliation of symptoms
- Inability to undergo conscious sedation or general anesthesia
- Coagulation disorder
- Total obstruction more than 4 to 6 weeks.

TABLE 32.2: Indications for laser/cryotherapy/ electrocautery/APC

Benign or malignant airway lesion associated with:
Dyspnea
Uncontrolled cough
Impending asphyxiation
Stridor
Inability to wean from ventilator owing to obstruction
Post obstructive pneumonia
Symptomatic or unresolving atelectasis
Nearly complete (>50%) obstruction of one major bronchus
Recurrent hemoptysis
Closure of bronchopleural fistula not responsive to conventional therapy.

A potential catastrophic intraoperative complication of laser therapy is endotracheal fire. Although the use of combustible anesthetic gases must be avoided, the use of supplemental oxygen should be less than 40%. Although the metal rigid bronchoscope cannot catch fire, the use of the Nd:YAG laser through an endotracheal tube deserves special consideration. An immediate danger to the patient and operating room personnel is that of intratracheal explosion, with the anesthetic gases or oxygen producing a "torch effect" with the ignition of the endotracheal tube; longer-term complication may result from the subsequent lower airway inhalation injury, with mucosal sloughing and airway obstruction caused by granulation tissue. Similarly, a silicone stent should be removed prior to the use of laser therapy.

Fatal hemorrhage is associated with perforation into an involved or contiguous vascular structure. Perforation may also occur into adjacent structures with the development of pneumothorax, pneumomediastinum and tracheoesophageal fistula. Systemic air embolism and the development of vascular communication with the tracheobronchial tree have been reported.

Technique

Physicians prefer to use rigid bronchoscopy with general anesthesia, although procedures can be performed through the flexible fiberoptic bronchoscope using topical anesthesia alone.[65,66] Laser resection is performed first with photocoagulation of the tumor. Coagulated tissue is then removed by the use of the beveled edge of the rigid bronchoscope. Complete laser vaporization of tissue may also be performed, but has high risk of endobronchial fire. The laser beam should always be aligned parallel to the bronchial wall and never be discharged perpendicular to the airway wall. Laser pulses of one second or less are usually employed. When using a flexible bronchoscope, the removal of devitalized tissue can be slow and difficult due to small forceps. In addition, the flexible bronchoscope is combustible.

Precautions

The patient's eyes should be protected with saline-soaked pads and aluminum foil to avoid injury from accidental laser scatter, and all personnel should wear protective goggles. Fraction of inspired oxygen should be kept below 40%. Flammable materials, such as endotracheal tubes and silicone stents should be removed prior to the use of laser. If a flexible bronchoscope is employed, the laser must be kept at a sufficient distance beyond the tip of the bronchoscope. Power settings of greater than 40 watts should not be used.

Outcomes

The indications depend on the anatomic characteristics of the obstructing lesion and the clinical conditions outlined in Table 32.2.[66,67] Benign and malignant airway endobronchial lesions causing symptomatic or obstructive complications do benefit from endoscopic laser photoresection.[68-72] Laser therapy has also been performed for stenosis related to prolonged intubation;[73] stricture produced by mycobacterial infection; anastomosis granulation tissue following lung transplantation;[74] suture granulomas;[75] and in systemic inflammatory conditions, such as Wegener's granulomatosis, Behçet's syndrome and relapsing polychondritis.[76,77] Laser therapy has been also used in symptomatic obstruction secondary to broncholithiasis.[78] Benign or low-grade tumors, such as hamartomas, spindle cell carcinomas, endobronchial Kaposi's sarcomas, and even diffuse papillomatosis have also benefited from Nd:YAG laser photoablation.[79-82] A primary goal of laser therapy is the safe, effective, and rapid palliation of symptoms owing to tracheal or bronchial obstruction.

Electrocautery

Electrocautery uses electric current to produce heat and destroy tissue. Strauss[83] used electrocautery for treating gastrointestinal tumors in 1913 and reported their experience on over 40 cases in 1935.

Electrocautery uses alternating current at a high frequency (105 to 107 Hz) to generate heat that coagulates, vaporizes or cuts tissue, depending on the power. The power applied to the electrocautery device (measured in watts) corresponds to the heat generated in the tissue, as related by the equation: Power = $(\text{current})^2 \times \text{resistance}$. Coagulation involves high amperage and low voltage, whereas vaporization uses high voltage and low amperage. Cutting tissue with the ability to coagulate blends these two settings. At the temperature of approximately 70°C, the tissue coagulates and at over 200°C, the tissue carbonizes. The degree of destruction depends on the applied power, the electrical properties of the tissue, the device-tissue, contact time, and the device-tissue contact surface area.

When a tissue is sufficiently heated, cellular water evaporates, thereby destroying the cell and then the tissue. Heating to higher temperatures leads to the chemical breakdown of the cell and the tissue constituents and eventual vaporization/carbonization. Electrocautery devices are monopolar; they require the bronchoscope, the generator, and the patient to be grounded to complete the circuit or otherwise shocks and burns may occur. The bronchoscope should be insulated. The generator should at least have an isolated power output to minimize current leakage and possible injury, if it is not grounded.

Indications

The indications and contraindication for electrocautery are similar to those Nd:YAG laser[84,85] (Tables 32.1 and 32.2). Similarly, laser therapy electrocautery produces the rapid debulking of a tumor, but at a lower cost.

Equipment and Technique

Insulated flexible bronchoscopes with working channels of 2.0 or 2.6 mm are used. Electrocautery blunt-tip probe snare is compatible with the most commonly used flexible bronchoscopes. The generator should regulate the high-frequency current, so that operator can adjust the setting depending on whether the procedure is intended to coagulate, cut, cut and coagulate, or vaporize. The monopolar unit must be grounded with an electrode pad.

The operator can use either a closed forceps or the blunt electrocautery probe to manipulate the lesion and thus to assess its size, mobility, friability/bleeding potential, and to locate any attachment to the airway. Polypoid lesions may be amenable to the snare. The snare is used to cut and remove tissue, a blended current is used to cut and coagulate, but not vaporize.

Outcomes

It had been shown that hemoptysis was controlled in 75% of the cases, dyspnea was alleviated in 67%, and cough or stridor was relieved in 55%.[86] In one series, 28 of 29 patients had symptomatic improvement after the removal of a lesion, with a snare while another showed that 15 of 17 treated patients had immediate restoration of a patent airway; eight had relief of dyspnea, and four had control of hemoptysis.[87,88] Most series involve predominantly malignancies, and success is defined as removing greater than 50% of the tumor; success rates of 70 to 95% have been reported.[89-91]

Complications

Two endobronchial fires have been reported during the electrocautery procedure;[90] both were associated with high inspired oxygen concentrations, and in one incident, a silicon stent also ignited. Several investigators have reported hemorrhage, in most cases minor. One death had occurred secondary to hemorrhage. Operator and patient burns and electrical shocks are frequently mentioned as possible complications, but published data are scant. Another concern is using electrocautery in a patient with a pacemaker or an automatic implantable defibrillator because the devices may malfunction. When used in animal models, airway stenosis and cartilage damage have been shown to occur with electrocautery.

In summary, similar to Nd:YAG laser therapy, electrocautery is an effective tool for palliation. It is also a cheaper alternative to laser therapy, and has no significant disadvantages.

Argon Plasma Coagulation (APC)

Argon plasma coagulation is an electrosurgical technique used to remove an obstructing lesion and/or to achieve hemostasis. The indications and contraindications are similar to that of laser or electrocautery (Tables 32.1 and 32.2).

APC was developed more than 20 years ago to improve surgical hemostasis. In the early 1990s, a flexible probe was introduced that facilitated its use during endoscopic procedures. APC was initially used during gastrointestinal endoscopy during polypectomy.[92] APC has been used during bronchoscopic procedures to debulk malignant airway tumors, control hemoptysis, remove granulation tissue from stents or anastomoses, and treat a variety of other benign disorders.[93-97] APC is a noncontact form of electrocautery.

Procedure

Similar to electrocautery, a grounding pad should be placed on the patient back. It is applied at a power of 30 watts and an argon flow rate of 0.8 to 1 L/min, the flow rate determines the length of the flame. Since the argon will seek biological tissue or any combustible object, the flame length is important in its airway application. The probe tip should be several centimeters beyond the bronchoscope's tip. This insures that the bronchoscope will not get burned. The probe tip should be within 1 cm of the target lesion. The electric current will not be conducted if the probe is farther from the target lesion. The probe tip should not contact the target lesion. Argon gas is expelled from the probe and a high voltage electric current is passed. When the electric current contacts the argon gas, the argon gas becomes ionized and conducts a monopolar current to the target lesion.[94,95] This argon plasma is applied to the surface in one to three second bursts. The net tissue effect is similar to that of electrocautery.

In the process of debulking of an endobronchial lesion, the Eschar is first formed (Fig. 32.3) with the application of APC and then removed with forceps or a cryotherapy probe. APC is then applied to the underlying fresh tissue. This process is repeated until the tumor is removed. If brisk bleeding is encountered, the argon gas can be used without ignition to blow the blood away, thus improving visualization.

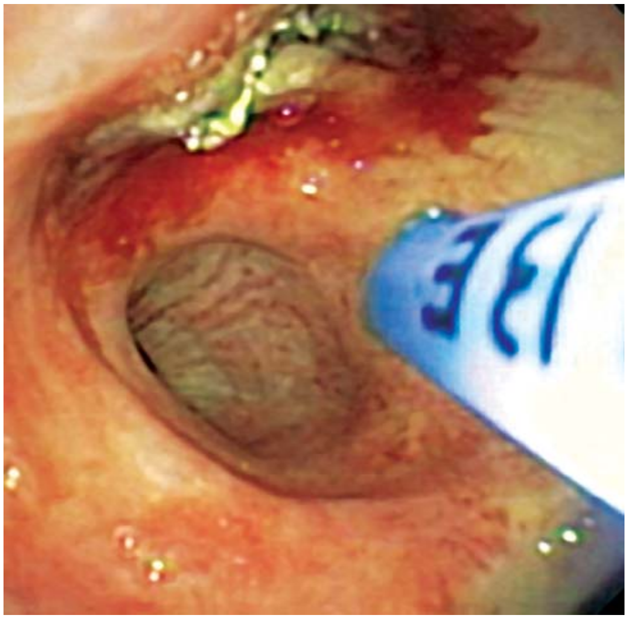


Fig. 32.3: APC use with an Escher formation

Outcomes

A prospective cohort study of 364 patients who underwent APC (482 procedures) reported a success rate of 67%, defined as hemostasis and/or full or partial airway recanalization; rigid bronchoscopy was used in 90% of the interventions.[96] In another study on 60 patients who underwent APC (70 procedures), treatment was immediately successful in 59 patients.[96] All of the patients had either hemoptysis or airway obstruction, with treatment success defined as the resolution of hemoptysis and/or decreased airway obstruction. Hemoptysis did not recur over a mean follow-up of 97 days, improved dyspnea persisted for over a mean follow-up of 53 days. A similar study of 47 patients reported a success rate of 92%, maintained for a mean follow-up of 6.7 months.[94] However, an average of more than three sessions per patient were required to achieve this result. APC has been successfully used to treat benign disorders, such as granulation tissue due to stents or airway anastomosis.[95,96]

Complications

Complications of APC are infrequent (less than 1% of procedures). They include airway burn and perforation, which can cause pneumomediastinum, subcutaneous emphysema and pneumothorax.[98] Gas embolism has also been described in a case series, leading to three cases of cardiovascular collapse and one case of death.[99] Such a complication is a reflection of the lack of experience by the operator. A burned bronchoscope has also been reported. Limiting the inspired oxygen concentration, the power (less than 40 watts), and the application time (less than 5 seconds) probably minimizes the risk of airway fire. Keeping the probe tip several centimeters away from any combustible material is also helpful to prevent airway fire.

Cryotherapy

Documents from 3500 BC described the use of cold as treatment for swelling and war wounds.[100] Hippocrates described the use of cold to treat orthopedic injuries.[100] Arnott described the use of salt solutions containing crushed ice at a temperature of about –8 to –12ºC to freeze advanced cancers of accessible sites, producing reduction in tumor size and improvement of pain.[101,102] The current cryoprobes function, according to the Joule-Thomson effect, i.e. the sudden expansion of a gas from a high to a low-pressure region.

The destructive effect of cold had been confirmed also by the healing of the tracheobronchial tree, with the restoration of a normal ciliated epithelium, without stenosis.[103-110] The first study from the Mayo Clinic, consisting of 28 patients with endobronchial tumors and concluded that cryotherapy did serve as a good alternative for palliation.[110]

Cryotherapy deals with the destruction of biological materials through the cytotoxic effects of freezing. The damage induced by freezing occurs at several levels, including at the molecular level, cellular level, structural level and the whole tissue. The effect of freeze injury is influenced by many factors and the survival of cells is dependent on the cooling rate,[111-113] the thawing rate,[114] the lowest temperature achieved[115] and repeated freezing thawing cycles.[116,117] Certain tissues are cryosensitive (skin, mucous membrane, granulation tissue), and others cryoresistant such as fat, cartilage, fibrous or connective tissue. The cryosensitivity depends on the water content of the cells (Table 32.3). Tumor cells may be more sensitive than normal cells.[118]

TABLE 32.3: Cryosensitive and cryoresistant tissues

Cryosensitive	*Cryoresistant*
Skin	Fat
Mucous membrane	Cartilage
Nerve	Nerve sheath
Endothelium	Connective tissue
Granulation tissue	Fibrosis

Cooling Agents

Several cooling agents can be used as cryogens. These are generally used in the liquid phase, on vaporization they remove heat at a constant temperature (heat of vaporization). The core temperature needed for a lesion to be destroyed is between –20 and –40°C. Freezing to –40°C or below at the rapid rate of –100°C per minute will cause more than 90% cell deaths.

Nitrous Oxide (N_2O) is the commonest cooling agent used. The vapor haze of N_2O occurs at the metal tip of the cryoprobe where it expands from a high pressure to atmospheric pressure (Joule-Thomson effect). This expansion lowers the temperature of the fluid and produces droplets of liquid and reaches equilibrium of –89ºC at atmospheric pressure.

Cryotherapy Equipment

The cryoprobes are rigid, semirigid or flexible; rigid and semirigid cryoprobes can only be used through a rigid bronchoscope, but flexible can be used through the channel of the fiberoptic bronchoscope. The diameter of the flexible probes requires a larger working channel (2.6 to 3.2 mm).

The monitoring of the freezing remains a problem,[119] there is no ideal solution. The empirical method relies on the experience of the operator, who depends on the change in color\consistency of the frozen tissue, and the length of freezing. In clinical studies,[120-123] each freeze-thaw cycle is about 30 seconds. The thaw phase is almost immediate with rigid probes that have a system of reheating, but with the flexible probes thawing is done by body temperature thus, increasing the freeze/thaw cycle times.

Indication

Cryotherapy is indicated for tracheobronchial obstruction. The selection criteria are similar to those of laser, APC or electrocautery (Tables 32.1 and 32.2) except when there is an urgency to treat. In addition, cryotherapy can be used for the extraction of foreign bodies, blood clots and mucous plugs.

Technique

The flexible cryoprobe is passed through the working channel, which is visualized and directly applied to the tumor area. The cryoprobe is activated with a foot pedal. An ice ball appears within 30 seconds on the tip of the probe; two to three freeze thaw cycles, each lasting for one minute, are applied to the same or the neighboring area. The tip can be applied perpendicularly, tangentially or driven into the tumor mass. The tissues are frozen at –30 to –40°C. The cryoprobe is deactivated by the removal of the foot from the foot pedal.

The metallic tip of the cryoprobe is placed on or pushed into the tumor that produces circumferential freezing of maximal volume. Two to three freeze thaw cycles are carried out at each site. The probe is then moved 5 to 6 mm and another three cycles carried out in the adjoining area. The hemostatic effect of freezing is often sufficient to stop hemoptysis.

Outcomes

Walsh[124] reported the effects of cryotherapy on dyspnea, hemoptysis, cough and stridor. In his study, symptoms, lung function, chest radiography and bronchoscopic findings were recorded serially before and after 81 cryotherapy sessions in 33 consecutive patients. Most patients reported the improvement of symptoms, stridor and hemoptysis, they had an overall improvement in dyspnea. Several other investigators have noticed a subjective improvement in symptoms.[125-127] Successful cryorecanalization was achieved in patients with endobronchial tumors.[128,129] The flexible cryoprobe for symptomatic endobronchial tumor stenosis was successful for immediate treatment, but the safety remained a cause of concern. This can be potentially dangerous in inexperienced hands. This method has been helpful in getting a bigger biopsy sample.[129] The mean transbronchial biopsy specimen area was 5.82 mm^2 taken by forceps compared to 15.11 mm^2 obtained using the cryoprobe.[130]

There has been a renewed interest in the treatment of early stages of lung cancers. The French experience[131] reported by the GECC (study group on cryosurgery) was based on 36 patients with 44 lesions (*in situ* or micro invasive tumors); 42% of these patients had been treated for an invasive ENT or bronchial cancer. At one year, there was complete clinical and histological control of the tumor was achieved in 88.8% with a mean follow-up of 32 months. The mean survival of this population was 30 months.

Benign Tracheobronchial Lesions

Benign lesions have been treated with cryotherapy with very good results, particularly for granulomatous tissues; 100% had favorable results with no recurrence months or even years after treatment. Granulation tissue is very sensitive to the effects of cold. Nevertheless, when surgery is not possible, treatment with cryotherapy can yield good results, and several cases of carcinoid, cylindromas, and laryngotracheal papillomas have been successfully treated.

Removal of Foreign Bodies

Foreign bodies have been extracted with success using cryotherapy, this is most useful to remove friable and biological matter such as pills, peanuts, tooth, chicken bones and others. This is extremely helpful in the removal blood clots mucus plugs and slough.

Future Work

In the treatment of lung cancer, a local cryotherapy has been used for palliative care.[132] Forest[133-137] has demonstrated differential biological effects of these therapies and the benefit to combine them. As vascular changes occur after cryotherapy, intratumoral angiogenesis was also studied. Tumors were treated by cryotherapy and chemotherapy by the injection of vinorelbine or both. Tumors treated by cryochemotherapy presented a significantly reduced volume and the lower T/C ratio, confirming the benefit of a combined treatment.

Photodynamic Therapy (PDT)

Photodynamic therapy is used for endobronchial destruction of tumor and also in the treatment of early superficial lung cancer with the only available agent, Porfimer (Photofrin®). A dose of 2 mg/kg is injected intravenously slowly over 5 to 10 minutes. There is preferential retention in tumor cells and in vascular endothelium, the cytotoxic reaction of porfimer is selective for neoplastic cells.[138] After 48 hours, the tumor is exposed to light energy, which triggers the cytotoxic reaction. The absorption peak occurs at a wavelength of 405 nm. A wavelength of 630 nm is used for adequate penetration and destruction to a depth of 5 to 10 mm.[139]

The most commonly used design is a cylindrical diffuser, which emits light in a 360 degree arc near its tip. It is recommended initially to apply 200 Joules/cm treated; additional energy may be applied during a follow-up bronchoscopy, two days later, 200 J are generally applied with a dye laser. Tumor is visualized, the light fiber is introduced through the working channel and the light is delivered to produce the cytotoxic reaction. A repeat bronchoscopy is performed in 48 hours. First the debris and secretion are removed, then a second treatment is applied.

The most common adverse event of PDT is photosensitivity of the skin. The patient teaching on photosensitivity precautions is important. The patient is at risk at 4 to 6 weeks after injection, protective gear must be worn till then.

Outcomes

PDT has shown to have an excellent cure rate in early stage endobronchial cancer, i.e. carcinoma *in situ*.[140-144] PDT has been used for palliation with similar results with other endoscopic techniques, but significant skin phototoxicity. The relief of symptoms is similar with PDT compared to Nd:YAG laser.[145] As there is a significant burden placed on the patient to protect themselves from phototoxicity, our preference has been to limit the use of PDT only in superficial early lung cancer.

PDT provides a safe endobronchial option of possible cure of early-stage lung cancer. New photosensitizers with more specificity for cancerous tissue and less associated photosensitivity have been used in different countries, however yet without data from large clinical trials.

Brachytherapy

Background

Endobronchial radiation therapy by the use of an implanted source of ionizing radiation (brachytherapy) was first used in the 1920s. Yankauer reported on the implantation of radium into an endobronchial tumor using a bronchoscope and having the radium in capsules attached to a string that exited through the mouth.[146] In the mid-1980s, publications distinguishing Low-Dose-Rate (LDR) from High-Dose-Rate (HDR) brachytherapy appeared. LDR brachytherapy is usually defined as less than 2 gray (Gy)/hour and a total dose between 1500 and 5000 Gy, given over 3 days; HDR involves more than 10 Gy/hour, in which the total dose and the dose per session (fraction) varies. Fractions have varied anywhere from approximately 300 to 1000 Gy, and total dose from approximately 500 to 4000 Gy.

Henschke developed the remote afterloading device, thereby reducing radiation exposure to the health care staff.[147] Almost 20 years later, the use of the flexible bronchoscope and the polyethylene catheter that holds the radioactive material for brachytherapy was described.[148,149] Iridium-192, the current radiation source was also described at this same time.[148]

Techniques and Dosage

Currently, intraluminal brachytherapy uses fiberoptic bronchoscopy for the placement of after loading with the radiation source manually or with a remote afterloader polyethylene catheter adjacent to the tumor, the placement is verified by bronchoscopy and by radiograph. The dose rate of brachytherapy depends on the radioactivity of the radionuclide used. The apparatus designed to deliver HDR brachytherapy uses iridium 192, which is the radionuclide of choice. HDR brachytherapy is usually delivered in fractionated doses to maximize its safety and effectiveness. The treatment schedules vary in clinical practice, most patients are treated once a week or once every two weeks rather than once a day to minimize patient discomfort.

Indications and Contraindications

The indications are similar to any other endobronchial therapy discussed earlier. The goal of brachytherapy is to palliate symptoms caused by airway obstruction by tumor. Brachytherapy, however, can also be used as an adjunct to external beam radiotherapy for treatment in otherwise unresectable lung cancer. Some investigators[150] have used it in patients who have histologically positive surgical margins after resection.

Absolute contraindications for endobronchial brachytherapy include known fistulas to nonbronchial tissue areas and lesions that are not proven malignancies. Patients with endotracheal carcinoma causing high-grade obstruction should be treated with Nd:YAG laser and the possible placement of stent before brachytherapy, because of the potential for postradiation edema and total airway obstruction.

Outcomes

Most studies on brachytherapy have reported on its use in combination with external beam radiation therapy. Subjective improvement after brachytherapy has ranged from 20 to 100%, depending on the symptom. Hemoptysis is relieved in more than 90% of the treated patient, cough and dyspnea have moderate to minimal relief, probably owing to an underlying chronic bronchitis or radiation fibrosis. In most studies, there was a greater than 50% improvement in the patency of the airway. The positive response of most studies persisted for six or more months.[151-158]

Conventional external-beam radiation therapy relieves the symptoms of hemoptysis, dyspnea, or chest pain in 50 to 80% of patients for three to four months.[156] There are no studies comparing external-beam radiation therapy with endobronchial brachytherapy directly. Based on existing data, however, endobronchial brachytherapy has been a second line treatment option offering effective palliation.

Complications

Brachytherapy has both early and late complications. The two most serious complications of endobronchial brachytherapy are massive hemoptysis and fistula formation to the mediastinum. Serious complications range up to 42% in several large series. Risk of massive pulmonary hemorrhage is likely related to the proximity of pulmonary arteries to the left upper lobe bronchus. Bedwinek[157,158] found a 32% rate of massive hemoptysis with recurrent tumors in the right upper lobe, right mainstem, and left upper lobe bronchus.

Flexible Fiberoptic Balloon Dilation

The successful use of a balloon to dilate a benign airway stricture was first reported in an 18-week infant with a postsurgical stricture.[159] Those initial reports utilized fluoroscopy or rigid bronchoscopy to guide the dilation procedure. Flexible fiberoptic bronchoscopy with balloon dilation was not described until 1991,[159] and since that time relatively few reports with small numbers of patients have been published.[160-166] This technique is useful in the treatment of benign strictures due to sequelae of long-term endotracheal intubation, bronchial reimplantation, anastomosis of transplanted lungs, granulomatous disease (e.g. tuberculosis, Wegener's granulomatosis) or smoke inhalation. A suitable lesion for balloon dilation is a web-like stenosis (Figs 32.4A to C), but if there is loss of supporting structures, the success is poor. Medical treatment of the cause of the stricture should be instituted prior to attempt at dilation. For example, local treatment of patients with strictures secondary to tuberculosis should not be attempted until adequate antimicrobial treatment is administered.

Technique

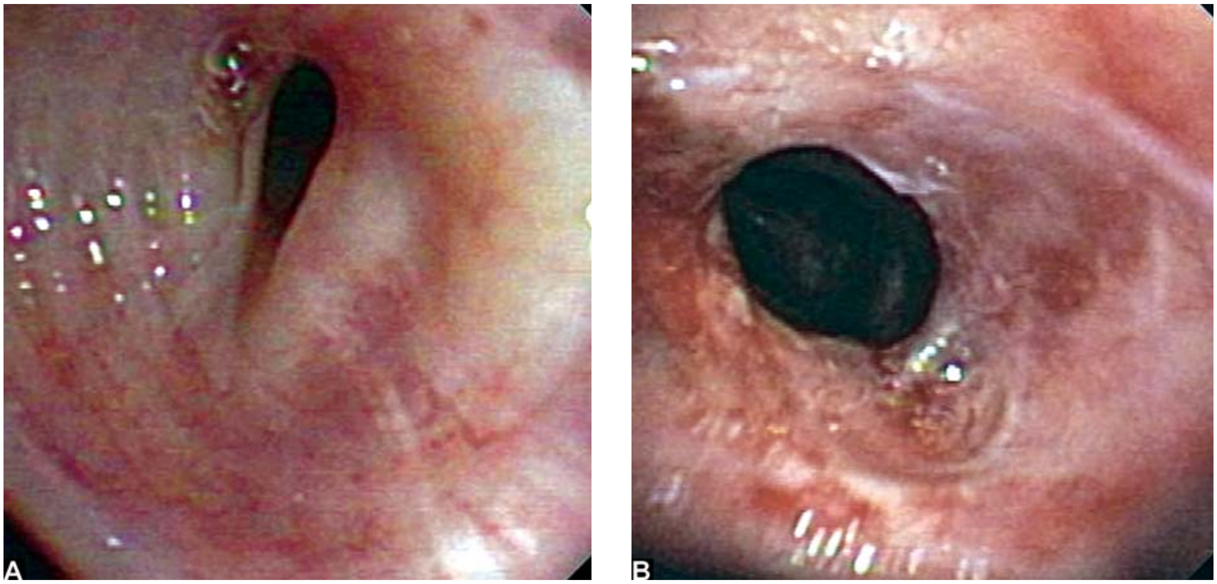
Bronchoscopic balloon dilation is a simple method to dilate a stenosis. A flexible fiberoptic bronchoscope is used in a standard manner with topical anesthesia and conscious sedation. After the identification of the stenosis, a 0.89 mm diameter guide wire is passed through the working channel and advanced beyond the stenosis and monitored fluoroscopically. The bronchoscope is removed once guide wire is in place. Next, a balloon catheter is passed, which has been selected based upon the diameter of the stenosis. The balloon has variable diameters, the dilation can start with the small size and then increased in size. The marking on the balloon, which is radiologically opaque, should protrude enough beyond each end of the stenosis for the dilation of the entire lesion. If the balloon does not extend distally enough, it tends to slip out of the stenosis upon inflation. If the balloon is ineffective, it should be replaced with a larger one. Repeated inflations can be performed with the same balloon if the result is inadequate. Immediate success or failure will be visible to the bronchoscopist (Fig. 32.5).

Complications

Excessive balloon inflation or a large length may lacerate or rupture the airway, but these complications have not been reported.

Outcomes

Several case series of fiberoptic bronchoscopic balloon dilation in adults have been reported. The largest series involved 19 stenoses in 16 patients; initial success was achieved in 13 of 19 bronchial stenoses; six dilations were unsuccessful because the stenoses were caused by localized bronchomalacia.[164-166] On an average about 50%



Figs 32.4A and B: Web like stenosis, which has been improved by balloon dilation

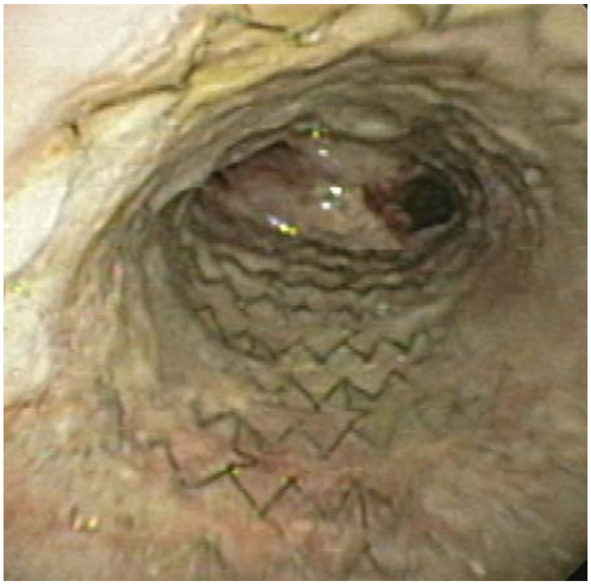


Fig. 32.4C: A metal placed

success rate has been reported without reinterventions. Surgical treatment of the stenotic segment is technically feasible in most patients. Endobronchial cryotherapy[166] in conjunction with balloon dilation has been used in two cases of benign airway stenosis with success. However, an airway stent is usually needed for support if there is damage to cartilage in the trachea or bronchi resulting in bronchomalacia.[166]

Airway Stents

The term "stent" honors a late 19th century British dentist, Charles R Stent, who developed a dental impression material that was later used as a template to support heal-ing skin grafts.[167] Today, the term stent connotes an artificial support that maintains patency of a hollow tubular structure. When the large airway is compressed by an extraluminal lesion (Figs 32.6A and B), airway

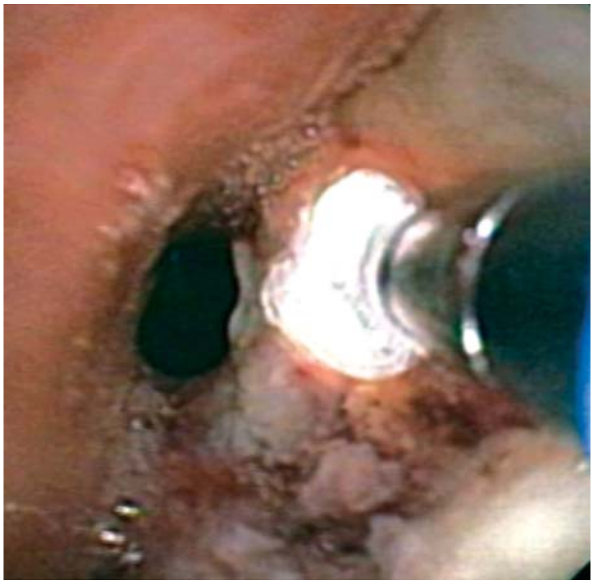

Fig. 32.5: Use of the cryotherapy

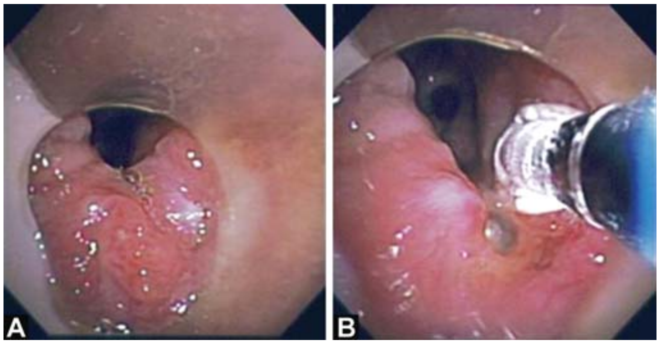


Figs 32.6A and B: Use of cryotherapy in granulation tissue formed after a stent placement

stents can play an important role. There is no ideal stent, but some characteristics make it more valuable, such as the ease of insertion and removal, infrequent migration, resistance to external forces, lack of tissue reaction, and improved mobilization of secretions.

Indications

Stent may be used alone or with other techniques for the palliation of dyspnea, cough, or respiratory insufficiency due to central airway obstruction. An airway stent supports the airway wall against collapse or external compression and can impede the extension of tumor into the airway lumen. Stents can be safely used in patients undergoing external-beam radiation therapy or brachytherapy.[64]

TABLE 32.4: Airways stents

Silicone Stents	*Metal Stents*
Rigid bronchoscopy	Flexible bronchoscopy
Removable	Extremely difficult to remove
High migration rate	Low migration rate
Thick caliber	Thin caliber
Infections	Infections
Mucostasis	Mucostasis
Granulation tissue formation	Granulation tissue formation

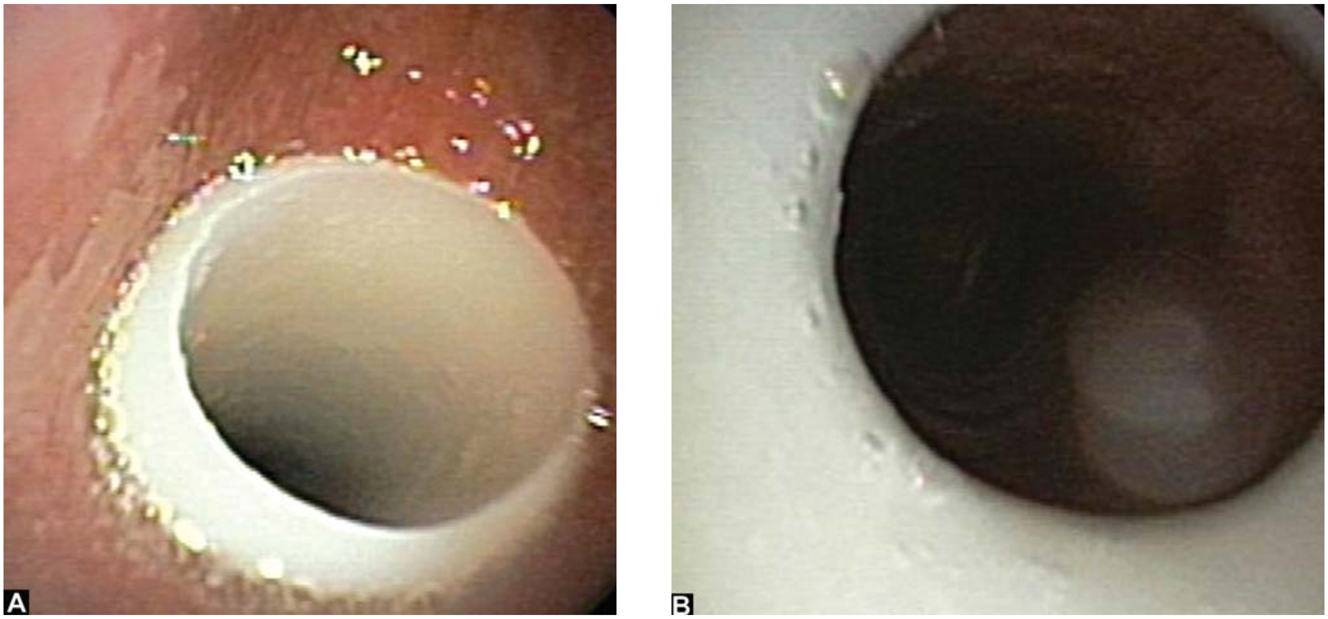
There is no survival difference between those patients without malignant airway obstruction who received palliative chemotherapy (median survival, 8.4 months) and others with airway obstruction who received treatment with laser, stent, or both followed by chemotherapy (median survival, 8.2 months).[168] The first choice to treat a benign stricture due to prolonged intubation, infectious or inflammatory diseases, and infectious diseases should comprise of a surgical repair. The patient may require stenting if there are comorbid conditions that do not allow surgery. There is an FDA black box warning against placing metal stent in a patient with benign stricture.

Types of Stents

Tracheobronchial stents can be grouped into silicone, metal or hybrid stents (Figs 32.7A and B). Silicone stents include Montgomery T-tube, Dumon, Polyflex, Noppen and Hood. The metal stents are available as covered or uncovered, include Palmaz, Wallstent Wallgraft, Ultraflex (Table 32.4). Finally hybrid stents are a combination of both such as Orlowski and Dynamic stents.

i. *Silicone stents:* The most widely used stent for central airway obstruction is the silicone stent. Silicone rubber is a synthetic substance made of silicone elastomers; it is firm, stable at high temperatures, and repels water. Silicone stents are relatively inexpensive and well tolerated. They can be repositioning and removed without difficulty. Disadvantages include stent migration, granuloma formation, mucous plugging, insufficient flexibility to conform to irregular airways, interference with mucociliary clearance, and a need for rigid bronchoscopy for their placement.

   Montgomery T-tube: In 1965, the Montgomery T-tube was introduced for the treatment of subglottic and tracheal stenosis.[169] A tracheotomy is needed to place this stent during operation or via rigid bronchoscopy.



Figs 32.7A and B: Silicone stent on the proximal end as well passing through the silicone stent

The limb protruding out of the tracheostoma is left open for cricoid or glottic stenosis, unplugged transiently for bronchial toilet, or closed to allow speech. Radial force is not required to hold this stent in position. Montgomery T-tube is a safe stent for subglottis stenosis.

Smooth-walled Hood stent: The smooth-walled Hood stent is one of the first silicone stents designed for use in the airway. It is a straight, smooth-walled silicone tube that can be ordered in varying lengths and diameters, or in the shape of "Y". This stent does easily migrate, the design has been now modified to include a small flange on its proximal and distal aspects. Nevertheless, stent migration still occurs.

Studded Dumon stent: Dumon[170] initially described his experience with a new dedicated tracheobronchial prosthesis made of silicone with studs to decrease the migration. The studded Dumon stent has become the most widely used airway stent in the world since its introduction and is now considered by many as the gold standard. The stent is manufactured in various diameters, lengths, and shapes, including straight, L-shaped and Y-shaped. The stent stays in place due to radial force and the studs, but still has a significant migration rate of about 10 to 13%.[171,172]

Reynders-Noppen Tygon stent: The Reynders-Noppen Tygon stent is not commercially available in the United States. It is a cylindrical tygon plastic tube molded into a screw-thread form, which is far more rigid than the silicone stents. It must be pushed into place along the outside of a specific introducer; it cannot be folded into an applicator with bronchoscopic introduction. One study compared the outcome of 50 patients treated with either studded Dumon silicone stents or screw-thread stents. Stent migration occurred in more patients who received Dumon stent (24% vs 5%), although the difference was not statistically significant.[173]

Polyflex stent: Polyflex stent is a self-expanding stent made of cross-woven polyester threads embedded in silicone. Stents of different lengths and diameters and tapered models are available for sealing stump fistula. In one study of only 12 patients, 16 stents were placed with a migration rate was at 75%.[174] These investigators have abandoned the use of polyflex stents.

ii. *Metal stents:* Various metals, such as stainless steel, tantalum, alloys incorporating cobalt, chromium, and molybdenum (Vitallium, Nobelium) are inherently inert and can be safely placed into living tissues. All metal stents are radiopaque, exhibit varying degrees of radial force, are easy to insert, and maintain ventilation when placed across lobar orifices. These stents can be further divided into fixed diameter stents, which require balloon dilatation, and self-expandable stents, which spring to a predetermined diameter once released. These stents could be either made of bare metal or have a thin coating with silicon, nylon or polyurethane. They can be placed in an outpatient

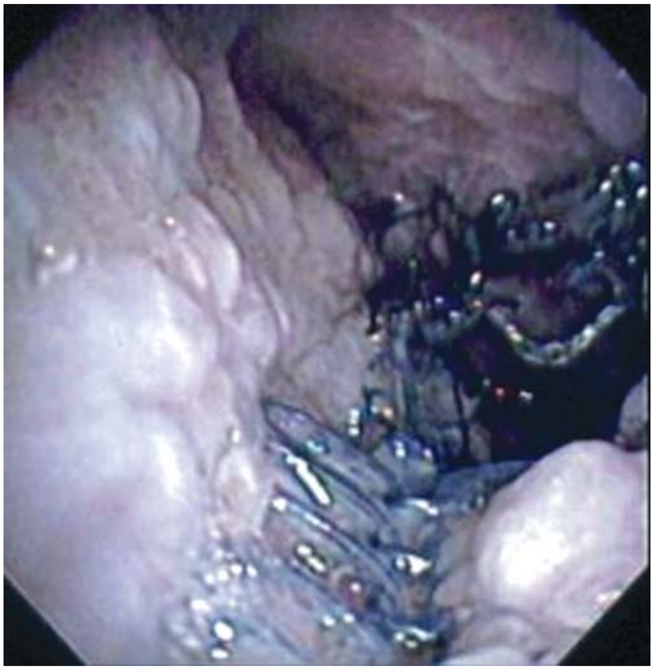


Fig. 32.8: Broken wire of a metal stent and granulation tissue

setting via flexible bronchoscopy under local anesthesia.[175,176] The ease of use has led to significant abuse and harm to patients. Its walls are thinner than a silicone stent and able to conform to tortuous airway. Similar to the silicone stent, granulation tissue formation does take place (Fig. 32.8). The disadvantage is the difficulty in removing and repositioning the stent; constant movement and metal fatigue leads to fractures of the wires. Metal stents migrate rarely (<1%).

Palmaz and Strecker stents: The Palmaz and Strecker stents are fixed-diameter balloon-expandable stents. These stents do not exhibit any intrinsic radial force, thereby compressive forces, such as breathing and coughing leads to the collapse of the stent, which in turn obstructs the airway. The plastic behavior of the Palmaz stent makes it unsuitable for use. Both these stents are of historical value and should not be used in the airway.

Gianturco stent: The Gianturco stent is made of a continuous loop of stainless steel wire, can be compressed into a narrow cylinder before bronchoscopic placement. Once expanded, the stent maintains an expansive force, and the small hooks embed in the airway mucosa to retard migration. Complications can lead to tracheopharyngeal fistula, and fatal erosion of pulmonary artery. The combination of high radial force exerted over the airway mucosa at selected contact points where the hooks are fixed can lead to mucosal ischemia and perforation.[177] Due to the severity of reported complications, this stent should also not be used.

Wallstent: Wallstent is a self-expanding device made of cobalt-alloy braided filaments in the form of a tubular mesh. It has a special feature of outward radial force provided by its integral design. It is inserted in a constrained form and once deployed expands to a preset diameter. The stent can be loaded into a delivery catheter. Various lengths and diameters are available. The covered form of the Wallstent prevents tumor and granulation growing through the spaces between the thin wire mesh. In a report of 52 Wallstents, stent-related obstructive granuloma occurred in 11% of patients, stent migration was not found. [178]

Ultraflex: The Ultraflex is a self-expanding stent made of nitinol, which is an alloy with shape memory, which deforms at low temperatures and regains its original shape at higher temperatures. Immediate relief of dyspnea is achieved in over 80% of the patients and migration is not observed.[179] The Ultraflex stents could be placed satisfactorily without fluoroscopy.[180] The complication rate was 0.06 complications per patient-month. The most common complications were infectious tracheobronchitis and obstructing granulomas requiring interventions to restore airway patency. Tumor growth and stent fracture were also seen.[180]

Alveolus stent: Alveolus stent is also self-expanding, completely polyurethane covered metallic stent. It has been claimed that it can be easily removed, but there is no data on this. The Alveolus stent is constructed from a single piece of nitinol, with concentric rings held in position by nitinol strands, this feature also makes it to crack vertically very easily. Due to its structure, it is amenable to length modification. Because it does not foreshorten with deployment and is completely covered in polyurethane coating, the stent keeps to its trimmed length and structural integrity.[181]

iii. *Hybrid stents:* Several stents incorporating both silicone and metal have been designed in an attempt to remedy some of the drawbacks of purely silicone or metal devices. Hybrid stents consist of expandable metal struts that resist compression, but are covered by a silicone membrane, which limits infiltration by tumor or granulation tissue.

The Rusch Y-stent: The Rusch Y-stent it is a Y-shaped stent made of silicone with a firm anterior wall that consists of horseshoe-shaped metal strut, which simulate the anterior trachea wall; the posterior wall is made of soft silicone, simulating the pars membranosa of the trachea. The stent can be difficult to insert. It is placed during rigid laryngoscopy by the means of a specially designed forceps, and the two distal limbs are inserted into the left and right main bronchi.[182] However, its length makes it difficult for patients to effectively clear airway secretions, and removal can be difficult if it becomes obstructed. It is used for strictures of the trachea, main carina and/or main bronchi; tracheobronchomalacia; tracheobronchomegaly and esophageal fistula.

Choice of Stent

The first issue to address is the proper selection of stent size. The length and diameter in relation to the dimensions of the trachea or bronchus are also important to avoid stent-related complications. Metal stents are more expensive than silicone. They are difficult, if not impossible, to remove. Silicone stents require specialized equipment, along with rigid bronchoscope, whereas metal stents can be inserted via flexible bronchoscopy. The ease of placement should not lead to the erroneous choice of the easiest stent over the best one to treat a given condition. The immediate and long-term complications should be thought of before a stent is placed. A check list suggested by Lee[183] is as follows:

1. Is a stent required?
2. Will the patient benefit from stent placement in terms of quality of life or prognosis?
3. Does the stent interfere or prohibit a curative surgical procedure later?
4. Do I have the expertise, equipment, and team to place the stent?
5. What is the underlying airway pathology and which stent is ideal?
6. Is it safe to place a stent in this anatomic site?
7. What are the required stent dimensions (length and diameter)?
8. Do I have the optimal stent or should I order a more appropriate one?”

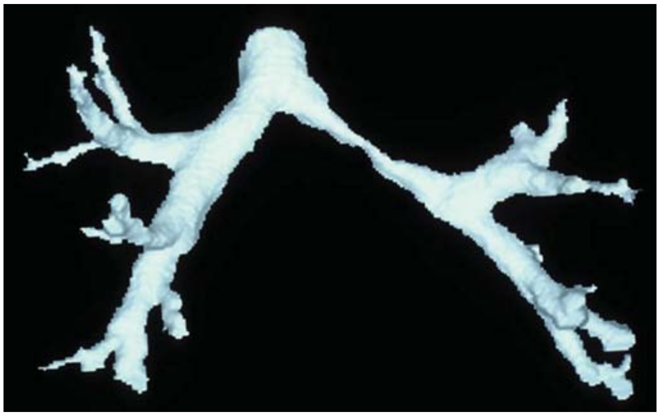

Fig. 32.9: Bronchial tree reconstruction shows an extrinsic compression of the left main stem bronchus

This check list will avoid errors and do less harm to the patient. In benign strictures, only silicone stent should be used as they are easy to remove and replace.

Technique

Bronchoscopy should be first performed in all patients with tracheobronchial stenosis. When a stenosis is evaluated, the distance from the vocal cords and the length and diameter of the lesion should be documented. A spiral CT scan with 3-D reconstruction is extremely helpful in the sizing of the stent that will be needed (Fig. 32.9). The largest possible prosthesis should be selected.

If a lesion is not amenable to endoscopic removal, bronchial dilatation should be done so that the stent of greatest diameter can be inserted.

The self-expanding stent that is mounted on an introduction catheter with crochet knots or is pushed out from the delivery system. The distal release model is easier to deploy than the proximal release design. The Polyflex stent with its pusher system is deployed with the help of a rigid bronchoscope. Insertion of the Dumon stent is facilitated by the use of the dedicated Dumon-Efer rigid bronchoscope and stent applicator set. Placement of dynamic and other bifurcated stents is facilitated with dedicated forceps.

In conclusion, airway stenting is a valuable adjunct to other therapeutic bronchoscopic techniques used for relieving central airway obstruction. Each stent has its unique features and complications. The technology is still in evolution, and design modifications strive to find the perfect stent.

Thoracoscopy

C Ravindran, Jyothi E

INTRODUCTION

Thoracoscopy or pleuroscopy is an invasive procedure to explore the pleural space through an incision in the chest wall. Thoracoscopy together with laparoscopy, was introduced in 1910 by Hans-Christian Jacobaeus, who at that time worked as an internist in Stockholm, Sweden. He published his first experiences in a paper entitled "On the possibility to use cystoscopy in the examination of serous cavities."[1] Jacobaeus himself initiated the therapeutic application of thoracoscopy for the lysis of pleural adhesions by means of thoracocautery to facilitate pneumothorax treatment of tuberculosis (Jacobaeus operation).[2] Between 1950 and 1960, a generation of chest physicians already familiar with the therapeutic application of thoracoscopy began to use the technique on a much broader basis for pleuropulmonary biopsy even for localized and diffuse pulmonary diseases. The excellent results of laparoscopic surgery and the tremendous advances in endoscopic technology stimulated many thoracic surgeons to develop minimally invasive techniques, which were termed therapeutic or surgical thoracoscopy, as well as Video-Assisted Thoracoscopic Surgery (VATS).[3-6]

Thoracoscopy is normally classified as:

- *Medical thoracoscopy:* This is a minimally invasive procedure, carried out mainly for diagnostic purposes by physicians, generally under local anesthesia and conscious sedation.
- *Surgical thoracoscopy:* Popularly known as VATS, is done by surgeons under general anesthesia for both diagnostic and therapeutic applications.[2]

MEDICAL THORACOSCOPY

Medical thoracoscopy is an invasive technique that should be used only when other, simpler procedures are not helpful. The technique is similar to chest-tube insertion by means of a trocar. In addition, the pleural cavity can be visualized and biopsy specimens can be taken from all the areas of the pleural cavity, including the chest wall, diaphragm, mediastinum and lung. An absolute prerequisite for thoracoscopy is the presence of an adequate pleural space, which should be at least 6–10 cm in width. If not present, a pneumothorax is induced under fluoroscopic or sonographic control, immediately or the day before thoracoscopy.

Medical thoracoscopic examination can be performed under local anesthesia or conscious sedation after premedication, without the support of an anesthesiologist. Furthermore, medical thoracoscopy is less expensive, can be safely performed with nondisposable instruments in an endoscopy suite.

Different techniques are used by the pulmonologists.[7,8] One of the methods consists of a single entry with a 9 mm thoracoscope with a working channel for accessory instruments, optical biopsy forceps and local anesthesia. The other method involves two entries, one with a 7 mm trocar for the examination telescope and the other with a 5 mm trocar for accessory instruments, including the biopsy forceps. Recently, minithoracoscopy was introduced mainly for the diagnostic purposes. The minithoracoscopy requires a rigid thoracoscope of 3 mm size, done under local anesthesia. For taking biopsy, a second port of entry is required unlike with the standard equipment.[9,10] Ultrasound can safely and reliably identify entry sites for the trocar placement during medical thoracoscopy, even in patients with pleural adhesions. The use of ultrasound may replace the practice of pneumothorax induction before medical thoracoscopy.[11]

Apart from the conventional white light, other imaging procedures that are said to yield more information especially for the presence of a pleural tumor, have been investigated, but the evidence has remained limited.[12-14] Narrow Band Imaging (NBI) is a new alternative light wavelength capture system that takes advantage of the altered blood vessel morphology. Wavelengths of light in the visible spectrum are filtered from the illumination source with the exemption of narrowbands in the blue and green spectrum centered at 415 nm and 540 nm, coinciding with the peak absorption spectrum of oxyhemoglobin making blood vessels more pronounced when viewed in NBI mode.[15] Imaging of vascular structures in deeper layers of thickened pleura can give some indication of where from the biopsy should best be taken. Moreover, NBI facilitates detection of any previously unobserved pleural dissemination.

Electrocoagulation is useful for the cauterization of adhesions and blebs or in the cases of bleeding after biopsy. For pleurodesis of effusions, 8 to 10 gm of sterile, dry, asbestos-free talc is insufflated through a rigid or flexible suction catheter with a pneumatic atomizer. Alternatively, 3 gm of talc may be used as slurry for nonmalignant effusion. Use of talc slurry is convenient and associated with excellent outcome and minimal complications.[16] For pneumothorax, 2 to 3 gm of talc is generally sufficient. Immediate suction through the chest tube is always applied following the procedure.

Equipment

Rigid instruments as they were from the beginning, are still in use (Fig. 33.1). They are preferred over the flexible instruments, which have several disadvantages compared to the rigid thoracoscope. The flexible instruments provide less adequate orientation within the pleural cavity, the biopsy specimens are small and frequently inadequate. A recently developed modification with a semiflexible tip can become an acceptable alternative.[17] Medical thoracoscopy can be performed either under direct vision through the endoscopic optics or indirectly by video transmission.[18] Single entry-site technique is usually done with a 9 mm diameter trocar and a cannula with a valve. Optical devices exist with various fields of view (0°, 30°, 90°). Trocars are also available with diameters of 5 and 3.75 mm for performing thoracoscopy in children. Biopsy forceps with straight optical devices, as well as accessory instruments, such as the puncture needle, cautery electrode, probe, combined suction and cautery cannula with valves and various biopsy forceps and scissors, are available. A talc atomizer (Fig. 33.2) is used for talc pleurodesis.[19,20]

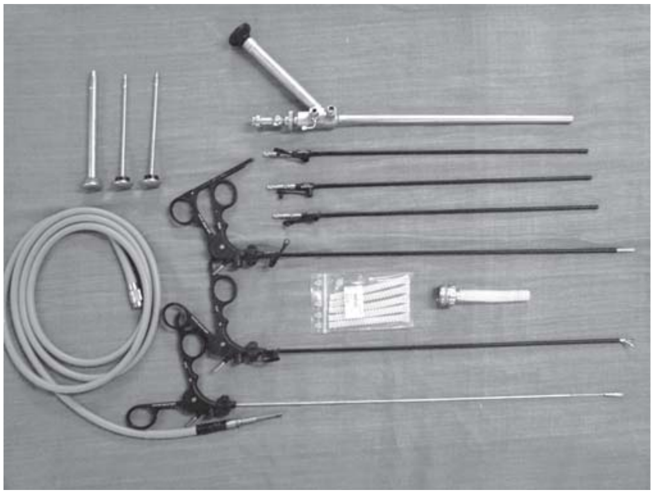

Fig. 33.1: Rigid thoracoscope and accessories

In the case of semirigid pleuroscope, the design including the handle is similar to a standard flexible bronchoscope, the proximal part being stiff (22 cm) with a bendable distal end (5 cm with angulation of 100 and 130 degrees). The outer diameter of the shaft is 7 mm. A working channel with a diameter of 2.8 mm allows the use of standard instruments that are available for flexible bronchoscope. The semirigid pleuroscope has the advantage that the skills involved in operating the instrument are generally familiar to the practicing bronchoscopist. Moreover, it is compatible with the existing video processors and light sources, so that little additional equipment is required to be added to the endoscopy suite. Its main disadvantage compared to the

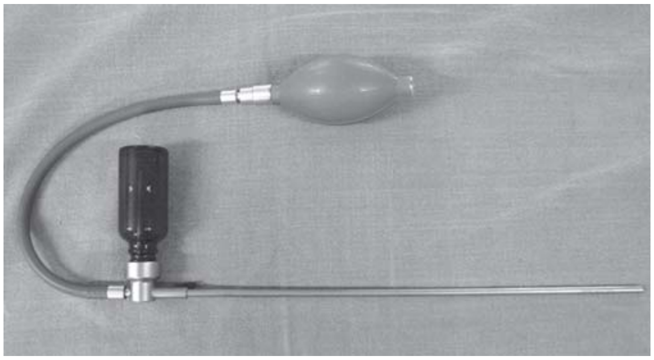

Fig. 33.2: Talc atomizer for pleurodesis

TABLE 33.1: Indications of medical thoracoscopy

Diagnostic	*Therapeutic*
Evaluation of undiagnosed exudative pleural effusion	Pleurodesis for malignant/recurrent pleural effusion/pneumothorax
Staging of malignant mesothelioma and lung cancer	Lysis of adhesion in pneumothorax/empyema
Biopsy from lung, diaphragm, mediastinum and pericardium	Sympathectomy

rigid thoracoscopic instruments is the smaller biopsy specimen. However, the flexible tip allows very homogeneous distribution of talc on all pleural surfaces where pleurodesis is required.

Procedure

Basic monitoring for medical thoracoscopy involves Electrocardiography (ECG) and pulse oximetry. Patient should lie in lateral decubitus position with the healthy lung on the dependent side. Ipsilateral arm should be placed above the head, so that the intercostal spaces become wider. Adequate local anesthesia should be given. The trocar is introduced with a rotating motion perpendicular to the chest wall. Once the trocar is introduced, suction is applied in the case of pleural effusion to remove the fluid. Adhesions can be lysed with a biopsy forceps or cautery. Exploration of the pleural space should be done by a slow circular motion of the scope. Biopsy can be taken from any abnormal lesion. At the end of the procedure, a chest drain is introduced in all patients.

Indications

Medical thoracoscopy unlike surgical thoracoscopy, is primarily used as a diagnostic procedure, but can be applied for certain therapeutic indications also (Table 33.1). The most common indications include the evaluation of the unknown exudative pleural effusion, staging of diffuse malignant mesothelioma or lung cancer, and treatment by talc pleurodesis of malignant or other recurrent effusions and empyema.[21] Medical thoracoscopy is also used for pleurodesis in recurrent pneumothorax. Other diagnostic indication is to obtain biopsies of the diaphragm, lung, mediastinum and pericardium. These procedures are safe in experienced hands, at the same time physicians should be aware of their limitations when indulging in procedures requiring more time and dissection.

Pleural Effusions

Even after extensive diagnostic evaluation of a patient with pleural effusion, the etiology often remains unclear.[22] Thoracoscopy is the standard diagnostic procedure for investigating exudative pleural effusion, it leads to a conclusive diagnosis for 95% of patients.[21] This should be performed in patients with undiagnosed effusions because of its high diagnostic sensitivity for malignant and tuberculous etiologies. The tissue obtained will usually provide a higher yield of the positive tubercular cultures, and greater histological proof of lung and pleural malignancies. The application of medical thoracoscopy allows the simultaneous insufflation of talc powder, which currently offers the best results in pleurodesis. Talc was used in 65% of 110 reported cases of nonmalignant pleural effusion that were treated with chemical pleurodesis, with a success rate of nearly 100%.[16] Further therapeutic advantages include complete fluid removal and adhesolysis in tuberculous effusion and empyema.

Malignant effusion: Malignant pleural effusion is the leading diagnostic and therapeutic indication for medical thoracoscopy.[23] In a prospective intrapatient comparison in 208 patients, the diagnostic yield of medical thoracoscopy was 95% versus 62% for pleural fluid cytology and 44% for percutaneous needle biopsy. Medical thoracoscopy showed a significantly higher sensitivity than needle biopsy plus cytology, which were positive in 74%. All methods taken together were diagnostic in 97% of cases of malignant pleural effusions. These results have been confirmed by others.[24,25]

In another series, no difference was noted in the yield for the different types of malignant pleural effusions: 96% in 67 cases of lung carcinoma, 96% in 154 cases with extrathoracic primary tumors, and 92% in 66 cases with diffuse malignant mesothelioma. The reasons for false-negative thoracoscopy results included insufficient and nonrepresentative biopsies, experience of the thoracoscopist, and the presence of adhesions (which denied access to neoplastic tissue).[23]

Medical thoracoscopy is helpful in the staging of lung cancer, diffuse malignant mesothelioma and metastatic cancer.[26] In the case of concomitant pleural effusion in lung cancer that otherwise appears resectable, medical thoracoscopy is indicated as a staging procedure to distinguish malignant from paramalignant effusion.[27] The latter condition would allow for the resection of the tumor; however, in 80 to 95% of the patients, the effusion is due to the tumor spread and surgical cure is not possible. Thus, medical thoracoscopy can help avoid unnecessary thoracotomy.

In diffuse malignant mesothelioma, medical thoracoscopy provides an earlier diagnosis, more precise histologic classification due to a larger, more representative biopsy, and more accurate staging.[26,27] This may have important therapeutic implications, as better responses to local immunotherapy or chemotherapy in stages I and II have been observed. Thoracoscopy is also helpful in the diagnosis of benign asbestos-related pleural effusion, which is a diagnosis of exclusion. Fibrohyaline or calcified, thick, pearly white pleural plaques indicate probable asbestos exposure. Thoracoscopic biopsies from lung and from certain lesions on the parietal pleura may demonstrate high concentrations of asbestos fibers, providing further support to the diagnosis of asbestos disease.[28]

In metastatic pleural effusions, biopsies of the visceral and diaphragmatic pleura are possible only under direct vision. Because the chest wall pleura is often not involved (in approximately 30% of cases) in early stages, it is not possible in these cases to provide a diagnosis by blind needle biopsy. With the large size of biopsy specimens obtained by thoracoscopy, it may be easier for the pathologist to suggest the origin of the tumor. In metastatic breast cancer, tissue can be obtained for the determination of hormone receptors. Even with lymphomas, the diagnostic yield, as well as the morphologic classification, are improved.[29]

Local treatment of pleural malignancies: The main therapeutic option offered by medical thoracoscopy is the prevention of recurrent effusion with pleurodesis. Under direct visual control, 8 to 10 gm of asbestos-free, sterilized talc (French talc) is insufflated into the pleural space so that the powder is equally distributed on the parietal and visceral pleura. Talc poudrage is probably the most effective, conservative option for pleurodesis.[19,20]

Tuberculous pleural effusion: Tuberculosis remains an important cause of pleuropulmonary involvement in developing countries. In extrapulmonary tuberculosis, pleural involvement is second only to lymph nodes. Although the yield of blind needle biopsy is higher than in pleural malignancies, the diagnostic accuracy of thoracoscopy is greater, because the pathologist is provided with multiple, selected biopsy specimens, and because the bacteriological culture proof of tubercle bacilli is more frequently positive. In a prospective intrapatient comparison, the histologic diagnosis of 100 patients with TB was established by thoracoscopy in 94%, compared with only 38% with needle biopsy, allowing an early start of antituberculous chemotherapy. The combined yield of pleural histology and mycobacterial culture was 99% for medical thoracoscopy, 51% for needle biopsy, and 61% when combined with fluid culture. The percentage of positive TB cultures was twice as high from thoracoscopic biopsy specimens, including cultures from fibrinous membranes (78%), compared with the percentage in pleural effusions and needle biopsy specimens, combined (39%). This had the advantages of an early bacteriologic confirmation and drug susceptibility testing. Resistance against one or multiple antituberculous drugs, which influenced therapy and prognosis, was found in 5 of the 78 positive cases (6.4%).[7]

In another prospective study of 40 patients from South Africa, thoracoscopy had a diagnostic yield of 98%, in comparison with an 80% diagnostic yield with Abrams' needle biopsies (three biopsy specimens were obtained, each examined histologically and microbiologically).[30] This led to the conclusion that in areas with a high prevalence of TB, Abrams' needle biopsy could contribute significantly to the diagnosis. In a further study on the effect of corticosteroids in the treatment of tuberculous pleurisy, the same authors found that the initial complete drainage of the effusion, performed during thoracoscopy, was associated with greater symptomatic improvement than with any subsequent therapy.[30]

Other pleural effusions: Thoracoscopy may provide clues to the etiology when effusions are neither malignant nor tuberculous as in the cases of rheumatoid arthritis, effusions following pancreatitis, hepatic hydrothorax, extension of disease from the abdominal cavity, or in effusion related to trauma. Although the history, pleural fluid analysis, physical and other examinations are usually diagnostic in these conditions, thoracoscopy is indicated in problematic cases. When pleural effusions are secondary to an underlying lung disease (such as pulmonary infarction or pneumonia), the diagnosis can frequently be made based on macroscopic examination, confirmed microscopically on lung biopsy. Thoracoscopy is also useful for the diagnosis of benign asbestos-related pleural effusions, which by definition present a diagnosis of exclusion.[31]

By the virtue of thoracoscopy, the proportion of so-called idiopathic pleural effusions usually decreases to less than 10%, whereas studies in which thoracoscopy was not applied, diagnosis is not established in more than 20% of cases. These figures will also depend on the

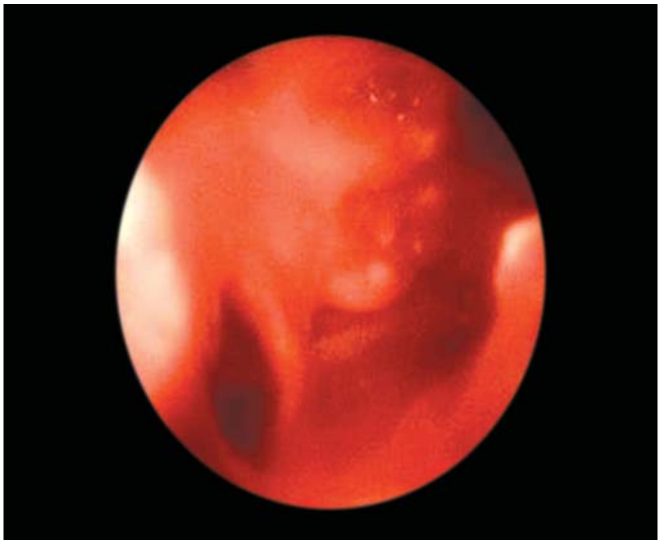

Fig. 33.3: Multiple nodules on visceral pleural surface in a case of hemorrhagic pleural effusion

selection of patients and the definition of an "idiopathic effusion".[32] In the selected cases of the recurrent pleural effusions of nonmalignant etiology, including chylothorax, pleurodesis may be induced by applying talc poudrage during medical thoracoscopy.[29]

The diagnostic accuracy of thoracoscopy in the setting of undiagnosed pleural effusions, varies widely with a range of about 60 to 90%.[28] Because of its high diagnostic accuracy, thoracoscopy is an excellent option in exudative effusion in which the etiology remains undetermined after pleural fluid analysis (Fig. 33.3). In a case series of 42 patients who underwent thoracoscopy at our center, 29 were done for diagnostic purposes, of whom 15 were diagnosed as malignant, 3 tuberculous and 10 of nonspecific inflammatory origin.[33]

Empyema

Medical thoracoscopy can be effectively used in the management of empyema.[24] This can help in breaking thin fibrinopurulent adhesions to remove multiple loculations and create a single cavity that can be drained and irrigated more successfully (Fig. 33.4).[34] This treatment should be instituted early in the course of empyema, before adhesions become too fibrous and adherent (Fig. 33.5). If a chest tube drainage is indicated and if the facilities are available, medical thoracoscopy should be performed at the time of chest-tube insertion itself. Medical thoracoscopy is a procedure similar to that of chest-tube insertion, at the same time it helps in visualizing the pleural cavity and allows better local treatment. In carefully selected cases, medical thoracoscopy can be useful, especially when performed early after the failure of chest tube drainage.[35] In more complex cases, VATS would be the preferred choice.[36,37]

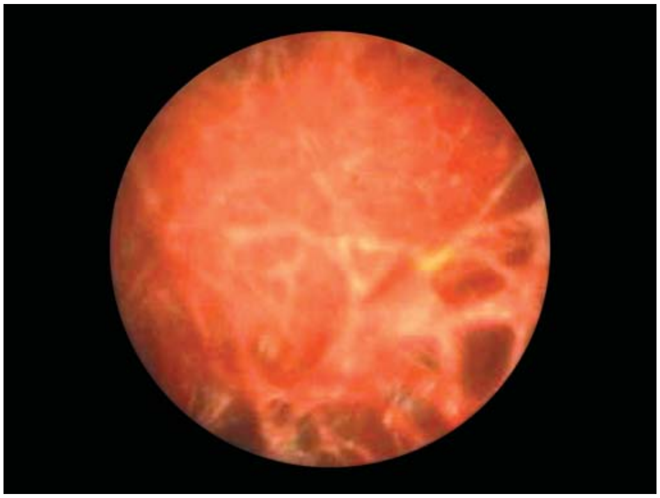

Fig. 33.4: Thoracoscopic view showing multiple thin adhesions

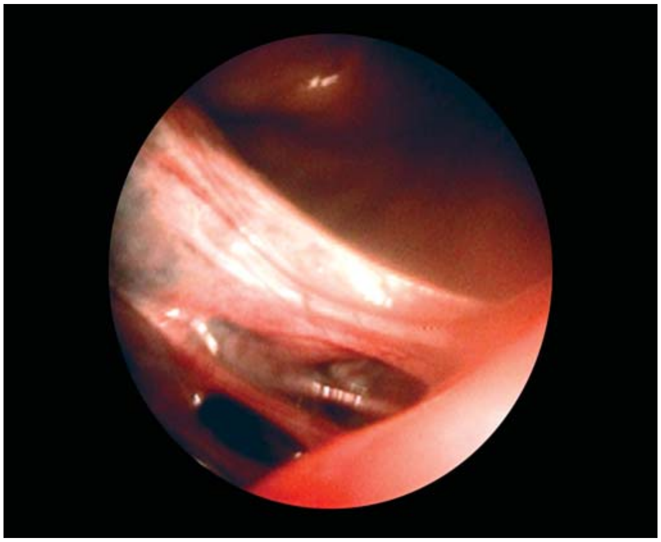

Fig. 33.5: Thick adhesion in tuberculous pleural effusion

Spontaneous Pneumothorax

In spontaneous pneumothorax, medical thoracoscopy can be used for both diagnostic and therapeutic purposes.[38] In particular, if a chest tube is introduced by a trocar technique, it is easy to visually inspect the lung and the pleural cavity before inserting the chest tube through the cannula. On inspection during medical thoracoscopy, the underlying lesions can be directly assessed according to the classification of Vanderschueren: Stage I with an endoscopically normal lung; Stage II with pleuropulmonary adhesions; Stage III with small bullae and blebs (< 2 cm in diameter); and Stage IV with numerous large bullae (> 2 cm in diameter).[39] Although the detection rates of blebs and bullae are higher in the series with VATS or thoracotomy, larger bullae, blebs or fistulae are likely to be detected during medical thoracoscopy.[38,39]

Medical thoracoscopy offers the possibility of combining pleural cavity drainage with the coagulation of blebs and bullae, as well as of pleurodesis by talc poudrage. Talc poudrage achieves the best conservative treatment results with the recurrence rates of less than 10%. In stage IV with numerous large bullae, VATS or thoracotomy should usually be performed. Talc poudrage and/or coagulation of bullae are performed only in patients in whom surgery is contraindicated because of the respiratory insufficiency secondary to advanced pulmonary disease.[16] Medical thoracoscopy is justified in all patients with spontaneous pneumothorax when tube drainage is indicated, as it provides a chance to assess the underlying lesions under direct vision; direct treatment by coagulation of blebs and bullae; severance of adhesions; administration of talc poudrage; and selection of the best location for chest-tube placement.

Advanced Indications

Lung biopsy: Forceps lung biopsy with or without electrocautery can be performed by pulmonologists using medical thoracoscopy (Fig. 33.6).[40] The results are comparable with surgical VATS biopsies in the diagnosis of diffuse lung diseases. Larger VATS biopsies are superior for conditions where lung vascular examination is necessary (e.g. vasculitis).

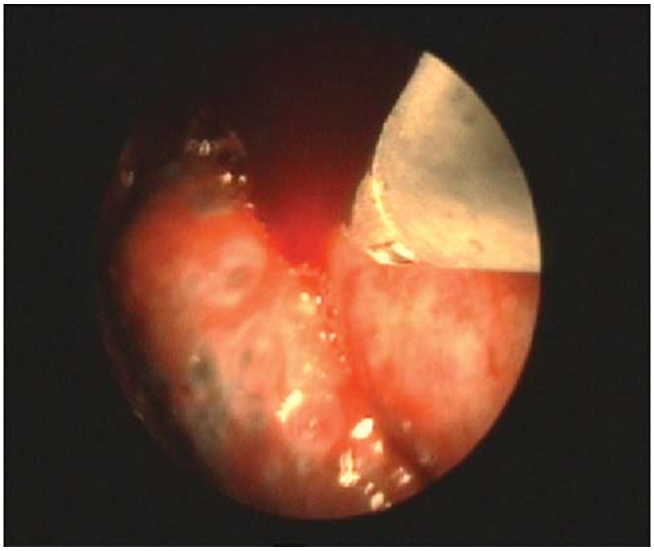

Fig. 33.6: Thoracoscopic pleural biopsy

Other thoracoscopic procedures, such as sympathectomy for the control of severe hyperhidrosis, can be easily performed by a well-trained thoracoscopist. Short- and long-term results are similar to those obtained by typical VATS interventions with a lesser degree of mortality.[4]

Contraindications

An obliterated pleural space is an absolute contraindication.[41] Relative contraindications include the presence of bleeding disorders, hypoxemia, unstable cardiovascular status, and persistent, uncontrolled cough.

Complications

During the procedure, cardiorespiratory function should be monitored by ECG, blood pressure measurement and continuous oximetry. Complications, such as benign cardiac arrhythmias, blood pressure instability, or hypoxemia can virtually be prevented by the administration of oxygen.

The reported mortality rates are very low (< 0.01%) (Table 33.2). Several liters of fluid can be removed during thoracoscopy with a little risk of pulmonary edema, since immediate equilibration of pressures is provided by the direct entrance of air through the cannula into the pleural space. If lung re-expansion appears to diminish, only low-pressure suction should be applied through the pleural drainage tube, which is always placed at the conclusion of the thoracoscopic procedure.

Following lung biopsy, a bronchopleural fistula may occur, requiring a longer period of suction than the usual three to five days, particularly in patients with poorly compliant lungs. After talc poudrage, fever may occur.

TABLE 33.2: Complications of thoracoscopy

1. During the procedure
    - Significant bleeding
    - Hypoxemia, cardiac arrhythmias, hypotension, occasionally death
    - Subcutaneous emphysema
2. Later complications
    - Local site infection
    - Empyema
    - Bronchopleural fistula
    - Respiratory failure
    - Neoplastic invasion of thoracoscopic tract

Local site infection is uncommon and empyema is rare. In the cases of mesothelioma, radiotherapy may be performed 10 to 12 days after thoracoscopy to prevent the late complications of tumor growth at the entry sites.

SURGICAL THORACOSCOPY

Video-assisted thoracoscopic surgery, often referred to as VATS, is done in a theater-suite under general anesthesia. Surgeons often use multiple ports to introduce the thoracoscope, biopsy forceps and suction cannulae. VATS is used to examine the chest cavity from within and to perform diagnostic procedures such as the lung, diaphragmatic and pleural biopsies.[42] Increasingly complex procedures are now being performed such as the lung resections, bullectomy, evacuation of pleural based problems, decortication, antireflux procedures, diaphragmatic plication and mediastinal node biopsy.[42,43] Thoracoscopic approach for the microsurgical removal of herniated thoracic disks is also described.[44] Compared to medical thoracoscopy, VATS is used for more complex, and time consuming procedures, replaces thoracotomy in many instances.

Post Thoracoscopic Management

Following thoracoscopy, a chest tube should be introduced into the pleural space. The tube is fixed in place by a skin suture. The tube is removed when there is no further air leakage or when the fluid production is less than 100 ml/day.[10] In uncomplicated cases, intercostal drain is removed after 48–72 hours.

34

The Burden and Clinical Spectrum of Respiratory Diseases

SK Jindal

INTRODUCTION

Infections, ever since they were first recognized, have dominated the scene of respiratory diseases all over the world for the past several centuries. It is only in the last fifty years or so that differences have cropped up in the spectrum of respiratory diseases between the developed and the developing countries. These are largely attributed to the differences in the economic, environmental, social and political standards, different health practices and the availability of health care infrastructure. It is apparent that the burden of infectious diseases in the developed countries has markedly diminished. On the other hand, the infections and the communicable diseases continue to pose a bigger challenge in the developing countries. What is most concerning is the observation that the burden of noninfectious or noncommunicable diseases in these countries is as enormous as that in the developed countries.[1,2] The future onslaught of respiratory diseases in countries, such as India, is expected to rise by manifolds. While infectious diseases will continue to persist, the noncommunicable, chronic diseases will increase at a rate even faster than that in the developed countries. This dual burden of both infectious and noninfectious diseases, which has already overstrained the health care infrastructure, will pose a major threat to its very existence.

RESPIRATORY DISEASE BURDEN

Respiratory diseases have a wide spectrum extending from acute conditions (such as pneumonias) at one end to the chronic conditions (such as the obstructive lung diseases) at the other end. The acute problems are often life-threatening, but the burden is difficult to assess. Community-acquired pneumonias may account for about 4–10 cases per thousand population per year.[3,4] Chronic respiratory symptoms together constitute the most frequent cause of outpatient clinic visits at primary levels of health care. In the community, there is about 12% prevalence of chronic chest symptoms such as cough and expectoration. Worldwide, in the Global Burden of Disease Study (GBDS), the Lower Respiratory Infection (LRI) was the first and tuberculosis, the seventh most common cause of disability assessed by using a standard unit, the Loss of Disability Adjusted Life Years (DALYs).[5] In the same study, Chronic Obstructive Pulmonary Disease (COPD) and tuberculosis were the sixth and seventh most common causes of mortality.[5] It has also been estimated that in the developing countries, by the year 2020, the diseases, such as COPD, LRI and TB, will continue to stay in the list of ten leading causes of loss of DALYs, with COPD being the fourth most common cause.

The total magnitude of the respiratory disease is expected to enormously expand in the next few decades. This is attributed to an increase in the total population, as well as to an increase in the exposure to the various risk factors, especially tobacco-smoking and the exposure to the environmental pollutants. The chronic respiratory disease is also a major cause of increased health care costs and economic burden in the community. The overall burden of several different chronic respiratory illnesses have now been recognized worldwide. This is also corroborated by the assessments of the Global Alliance against Chronic Respiratory Diseases (GARD), which aims at jointly fighting against this challenge and in improving the global respiratory health in accordance with the local needs.[6]

CLINICAL SPECTRUM OF RESPIRATORY DISEASES IN INDIA

There are four broad groups in which the respiratory problems can be broadly categorized: Acute diseases (both tubercular and nontubercular, bacterial, fungal and viral infections); airways and lung parenchymal diseases (e.g. asthma, COPD and interstitial diseases); neoplastic diseases (e.g. lung cancer and tumors of the mediastinum, pleura and chest wall); and respiratory critical illnesses (e.g. acute respiratory failure, severe pneumonia, sepsis, acute respiratory distress syndrome, pulmonary thromboembolism and others). Presently, the public burden of respiratory diseases in India is primarily constituted by tuberculosis, asthma and COPD (Table 34.1), but diseases, such as interstitial lung diseases, vasculitides, cardiopulmonary problems, lung neoplasms and sleep apnea syndromes are other major illnesses, which are being increasingly encountered in clinical practice.

TUBERCULOSIS

Tuberculosis, which continues to lead the list of major, but preventable health problems in India, accounts for nearly one-third of the total global burden. Nearly 40% of the Indian population is infected with the *Mycobacterium tuberculosis* and about 8.5 million individuals are estimated to suffer from "active" or "probably active" TB.[7,10] It also accounts for about 415 thousand deaths and for losses of more than 300 million in direct costs, each year.[7,10] The burden of TB is further aggravated because of the coexistence of problems of Multidrug Resistance (MDR), Human Immunodeficiency Virus (HIV) coinfection and other comorbidities. The rate of MDR-TB in new cases in India ranges from 0 to 3% at different sites, while it occurs in upto 13.0% of previously treated cases.[11] The problem of drug resistance is a major challenge, which is expected to rise in the immediate future. The recent recognition of Extreme Drug Resistant (XDR) TB in several different countries, including India, is an issue of grave concern.[11,12]

TABLE 34.1: Population prevalence rates (%) of major respiratory illnesses in general population in India

1.	Tuberculosis[7]	
	Infection	40.40%
	Prevalence: Sputum positive	0.23%
	Mortality	0.046%
	Overall prevalence	0.51%
2.	Bronchial asthma[8]	
	Children	2.3–12.5%
	Adults	2.4–3.5%
3.	Chronic Obstructive Pulmonary Disease (>35 years of age)[9]	
	M:	5.0%
	F:	3.2%

Fortunately, one can hope that the problem of TB will decline fast, once the results of successful implementation of the control programs are achieved. The Revised National TB Control Program (RNTCP), introduced in India since 1993, is now being implemented throughout the country.[10] The Program is aimed at the prevention and control of TB to achieve the Millennium Development Goals (MDGs) and related Stop TB Partnership of the World Health Organization. It adopts the strategy of Directly Observed Therapy (DOT) to prevent noncompliance and ensure the treatment of the diagnosed cases of TB. The evidence available till date shows a high success rate, promising a great degree of optimism.[13,14] The Program not only covers the governmental health-service institutions, but also the private sector, the medical colleges and other agencies engaged in providing health care. It also coordinates with the National AIDS Control Organization for patients with TB and HIV infection. It has already entered into the next phase of Stop TB Partnership with DOTS-Expansion to cover treatment for MDR-TB.

NON-TUBERCULOUS RESPIRATORY DISEASES

Bronchial Asthma

There is a lot of variability in the prevalence rates of asthma reported from different countries.[15,16] These variations can be attributed to the differences in the environmental and climatic risk factors, the genetic predisposition and the inheritance patterns.[15] Other important reasons, which can be counted for the difference include the differences in the definitions used for the diagnosis of asthma, the type of sample selection and the methodologies employed in different studies.[15-17] Frequently, the episodes of upper respiratory tract catarrh (especially when recurrent), chronic bronchitis, bronchiectasis and miscellaneous causes of cough, breathlessness and other respiratory symptoms are also inadvertently misdiagnosed as asthma. The prevalence rates and burden will also differ if one employs the definitions of "ever-asthma" or "current asthma," "symptomatic asthma" or "asthma, including bronchial hyperresponsiveness." Several of the global estimates of "current-asthma" point to variable rates from 1.2 and 3.7% in Belgium to as high as 25.5% in Australia.[15] The prevalence rates are also different if one uses the definition of "diagnosed asthma," "recent wheeze" or "Airway Hyperresponsiveness (AHR)".

The mean prevalence of clinical asthma for Southern Asia (Bangladesh, Bhutan, India, Nepal, Seychelles and Sri Lanka) was assessed to be 3.5% for a total population of 1.21 billions,[15,16] but several of these estimates, based on limited data from a particular region, do not truly represent the overall population prevalence. From India, the prevalence rates as high as over 10% among school children are reported in some studies. The field prevalence of diagnosed asthma is about 5% in children and about 3% in adults (Table 34.2).[8,18-30] The average population prevalence was 2.4% amongst 73,605 adults of over 15 years of age, studied at four different centers in Phase I of the Indian Multicentric Study on Epidemiology of Asthma, Respiratory Symptoms and Chronic Bronchitis in Adults (INSEARCH) when a validated questionnaire and a relatively stringent definition of "ever-asthma" were used.[21]

The most recent Phase II of the INSEARCH Study conducted in 12 different centers in a population sample of 1,69,575 individuals has reported a mean prevalence of 2.05% of current asthma[31] (Fig. 34.1). This reflects an enormous overall burden of asthma in India. For a total population of 1.028 billion (including children and adults) as per Census of India (2001), the minimum burden of asthma is about 21 millions for all age groups. The figure could actually be higher considering the higher prevalence rates in children. If one uses more sensitive criteria, such as the "wheeze alone" or the presence of bronchial hyperresponsiveness, the estimates are likely to be higher. These prevalence rates, although somewhat lower than those described from the West, are similar to those obtained from other Asian countries.[16,32] Some of the possible explanations, which have been advocated for a lower prevalence of asthma, may include the presumably protective influence of a higher incidence of childhood respiratory infections and ambient atmospheric pollution, which may partially suppress the allergic immune responses. A higher likelihood of breastfeeding in the Asian children may also be partially protective.

Asthma is more common in boys in childhood, but in women it is more commonly encountered among adults.[31] Residence in the urban areas and lower socio-economic status are other important factors likely to increase the occurrence of asthma. House-dust mites, contact with domestic-pets and exposure to a number of aeroallergens can precipitate and manifest asthma. Pollens of several plants, such as prosopis, ricinus, argemone, amaranthus, cannabis, parthenium, etc., have been implicated in the causation of asthma in India. Tobacco smoking of all types, including the cigarettes, "bidis" and "hukkah," as well as the passive exposure to Environmental Tobacco Smoke (ETS) form other important factors, which may provoke asthma.[33,34] Both "inutero" and childhood smoking exposure may also have an important role in the causation of asthma and

bronchial hyperresponsiveness in children, as well as in adults. Indoor exposure at home to pollutants from solid-fuel or fossil-fuel combustion may act in a similar fashion as the tobacco smoke. Their role in causing asthma, as well as in producing exacerbations has been described in the past, as well as in the INSEARCH Study.[31,35,36]

Food is commonly blamed for asthma in India, although only a few types of food can be definitely identified as triggers. The presence of Gastroesophageal Reflux (GER) is considered as an important trigger especially in patients with nocturnal asthma, though the relationship of GER with asthma has recently been disputed. It was shown in a large double-blind trial that silent GER was not a likely cause of poorly controlled asthma. Allergic Bronchopulmonary Aspergillosis (ABPA) is frequently recognized in about 10 to 15% of asthmatic individuals in India.[37] This is an important cause of difficult or poorly controlled asthma. At the primary health care levels, more than half of the ABPA patients are known to have received antitubercular treatment because of the similarities in the clinical and the radiological findings before the diagnosis is established.

Guidelines for the management of asthma formulated by the Global Initiative for Asthma (GINA) are now available for global use.[15] These guidelines are quite useful in the hands of physicians and the pulmonologists, especially those who practice at referral hospitals. A symptom-based, Practical Approach to Lung Health (PAL) is advocated for use at the primary health care.[38] Similarly, in India, a simple consensus-approach based on the global guidelines was developed under the initiative of WHO-Government of India Biennium program for use by the general practitioners and physicians, at the primary levels of health care.[39] The Indian guidelines for the primary levels of care follow a common and feasible algorithm to the management of asthma, in accordance with PAL plan.[39]

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease poses a huge burden from its disabling morbidity and mortality. Globally, it is perhaps the only leading cause of death that is increasing in prevalence.[40] The term COPD, which includes chronic obstructive bronchitis and emphysema in its ambit, has remained a source of confusion and controversy in the past. It was because of the lack of precise definitions and overlapping criteria for the diagnosis of chronic bronchitis and emphysema that the term was coined.[41] It is now globally accepted that COPD may be defined as a disease state characterized by airflow limitation that is not fully reversible and is associated with some systemic manifestations; the airflow limitation is usually progressive, but may show some degree of reversibility.[42] It is associated with an abnormal inflammatory response of the lungs to the noxious smoke and dusts.

Chronic obstructive pulmonary disease is distinct from asthma as it occurs in adults, generally over 40 years of age. Prevalence is high all over the world.[42,43] The burden of COPD is high in most of the Asian and the other developing countries, including India.[43-47] A prevalence of about 2 to 10% has been reported over the past 50 years in the form of several small reports (Table 34.3).[48-61] In the earlier multicenter Indian study on its epidemiology, the prevalence of 5% in men and 3.2% in women was reported amongst approximately 3,52,950 adult individuals who were over 35 years of age.[9,62] The INSEARCH (Phase II) Study at 12 centers, similarly reports the prevalence of 4.3% amongst men and of 2.7% amongst women.[31] The INSEARCH study had used only the standardized and validated bronchial-symptom questionnaire for the diagnosis of chronic bronchitis, as a prototype of COPD. On the other hand, the Burden of Obstructive Lung Disease (BOLD) initiative had used the questionnaire, as well as the spirometric parameters before and after bronchodilator administration.[44] The estimated population prevalence of COPD of Gold II stage from 12 sites amongst 8,775 adults was 10.1 ± SE = 4.8% overall.[44] Similarly, the PLATINO Study from Latin America, which employed spirometry, reported a prevalence estimate of 14.3%, the proportion of subject in Stages II-IV of the Gold classification was 8.6%.[45]

The disease is distinctly more common in smokers, with the smoker: nonsmoker ratio varying from over 2.65 to 1.[9] There is also a strong dose relationship, i.e. an increased risk of COPD with an increase in the amount and duration of smoking. All different forms of smoking prevalent in India, i.e. cigarettes, bidis, hookah, chilum and chutta are almost equally responsible for the causation of COPD. About 25 to 45% of patients of COPD have never smoked. A substantial incidence of COPD of 2.8 cases/ 1000/year in young adults was reported in an international cohort, comprising of 5,002 subjects without asthma from 12 countries in the year 1991-2002, for the framework of the European Community Respiratory Health Survey II.[63] Importantly, the presence of chronic cough and phlegm was helpful to identify a subgroup of subjects with a high risk of developing COPD, independent of their smoking habits.[63] Several different risk factors are important in such patients. Amongst nonsmoker individuals, especially the women, the indoor air pollution from passive exposure to tobacco smoke from others (e.g. husbands) and combustion of solid fuels are important risk factors.[9,31,63,64] Ambient air pollution from the dust, smoke and exhausts of vehicles and industrial units are significant contributory factors for the presence of chronic respiratory symptoms, as well as of COPD.[64,65]

The natural history of COPD is characterized by the progressive deterioration of lung functions, clinical symptomatology and frequent acute exacerbations usually due to recurrent respiratory infections. It is the most important and common cause of pulmonary hypertension, chronic cor pulmonale and chronic respiratory failure. The progression of COPD can be slowed and complications prevented with an appropriately devised treatment strategy. Smoking cessation is the most essential component of any treatment and rehabilitation plan for COPD. Long-term domiciliary oxygen therapy is the only other treatment option, which has shown to prolong survival and improve quality of life.

M: Male; F: Female; S: Smoker; NS: Nonsmoker; COPD: Chronic Obstructive Pulmonary (Lung, Airway) Disease

The importance of diagnosis, management and prevention of COPD is one essential step in the preservation of lung health. Based on the global Guidelines for Obstructive Lung Disease (GOLD), the Indian guidelines for its management, developed similarly as for asthma, are also available for use at the primary levels of health care.[42,66] One essential component in the comprehensive management of COPD is the need to recognize COPD as a distinct disease apart from asthma. The PAL strategy covers both asthma and COPD in the overall management and prevention plan.[38]

Environmental and Occupational Lung Diseases

There is an enormous increase in the incidence of general health problems and respiratory illnesses from exposure to different environmental pollutants. Outdoor atmospheric ambient-air pollution resulting from vehicular and industrial exhausts mostly in the urban areas is responsible for the increased presence of nonspecific respiratory symptoms and occurrence of pneumonias in children. Besides being responsible for causing and precipitating acute exacerbations of asthma and COPD, the continued exposure may also cause gradual and progressive decline in lung function. The limited number of studies, which are available on the subject from India, clearly point to a significant morbidity and mortality due to the problem.[67-70] In Delhi, a single-pollutant model based on air pollution levels and daily variations in respiratory morbidity during 2004-2005 showed that a 10 $\mu g/m^3$ rise in pollutant levels caused a statistically significant relative risk of respiratory morbidity.[67] In another study from Delhi, the chronic respiratory symptoms, as well as the prevalence of asthma and COPD were consistently and significantly more in the residents of higher-pollution areas.[69] Similarly, the residence in an industrial town in Punjab was associated with chronic respiratory symptoms and spirometric ventilatory defects, independently of other demographic variables.[68] Emergency hospital-visits and mortality were higher in the Delhi hospitals amongst patients from higher pollution areas.[70]

Indoor air pollution is similarly responsible for chronic nonspecific respiratory symptoms, respiratory infections and acute exacerbations of chronic respiratory and cardiovascular disease in India.[71-74] Indoor air pollution is an important issue of concern in both the urban and the rural areas. Indoor pollution in the ill-ventilated urban dwellings of multistorey buildings is attributable to large concentration of volatile organic hydrocarbons from the construction and building materials, paints, resins, cosmetics and toiletries, in addition to the presence of indoor allergens and microorganisms. The resultant "sick-building syndrome" characterized by mucosal irritation, respiratory symptoms and neurobehavioral impairments is now commonly reported amongst the inhabitants of all large towns and cities in India. Indoor radon-exposure is now listed as the second most common cause of lung cancer. On the other hand, indoor combustion of solid fuels for domestic cooking and heating is the most important source of indoor pollution in the rural and semi-urban areas, as well as the urban slums. In India, about 3.5% of the national burden of disease and over 0.4 million deaths are attributable to solid-fuel use.[72] Respiratory symptoms were observed in 13% of 3,608 nonsmoking women using domestic cooking fuels.[73] Use of Biomass-fuels was reported as an important factor for deterioration of lung function in both female and male subjects.[74]

Occupational exposure to inorganic dusts, chemicals, gases and fumes is rather rampant and largely unregulated in the developing world. This is especially so at the vast number of unorganized industrial and mining sites.[75,76] Unfortunately, we do not have systemically collected information on most of these problems. It is apparent from the reports appearing from time to time that pneumoconioses (such as silicosis, asbestosis and anthracosis) have a huge prevalence in India.[76-79] Silica is widely reported in upto 50% or more of miners and in workers engaged in iron and steel foundries; manufacturing of pottery, ceramic, glass, paints and rubber; slate-pencil and stone cutting units; and quartz-grinding, metal casting, scaling, polishing and other manufacturing processes.[76]

India imports about 1,00,000 metric tons of asbestos per year for mining and milling of small-scale asbestos.[79] Surveys showed a significant degree of occupational exposures, early radiological and lung function changes amongst asbestos-exposed workers.[79] It is anticipated that asbestos-related disease will account for more than a million deaths in the developing countries.[78] By the year 2020, the number of deaths is likely to begin to rise in the developing countries when it is likely to start declining in the developed countries.[78] Toxic-gas exposure due to industrial leaks or exhausts is another common problem of which the Union-Carbide disaster in Bhopal is an important reminder.[80] Reports on organic dusts exposure especially at work-places, which are responsible for hypersensitivity pneumonias are there, albeit anecdotal and small. Incidences of farmer's lung disease, byssinosis, bagassosis and aspergillosis have been reported from different places.[81-83]

Interstitial Lung Diseases

Interstitial Lung Disease (ILD) is a broad term, which encompasses over 150 different conditions and diffusely involves the lung parenchyma. ILDs in the past were either misdiagnosed or only those which occurred in association with systemic diseases especially the Connective Tissue Disorders (CTD), were recognized. "Lone" Interstitial Pulmonary Fibrosis (IPF), sarcoidosis, pulmonary vasculitides and even hypersensitivity pneumonias were generally considered rare. However now, both general and pulmonary physicians confront and diagnose these problems more frequently in their day-to-day practice. Several reports on these diseases have appeared in the Indian literature in the last two decades.[84,85] This trend is partly attributed to an increased awareness and a wider availability of better diagnostic techniques, but a genuine increase in the occurrence and incidence of these diseases is also understandable.

The two important ILDs, which have made a significant impact on the clinical practice, are sarcoidosis and the Idiopathic Interstitial Pneumonias (IIP).[86] The recent surge in the number of patients with these disorders, diagnosed in the medical and chest departments of mostly the large hospitals bears testimony to their increased occurrence. Sarcoidosis known in India since past four decades, has always posed a challenge in the differential diagnosis particularly from tuberculosis. The distinction between the two diseases is of great relevance especially because of the need of anti-inflammatory corticosteroid treatment for sarcoidosis, which in the case of tuberculosis is avoided for its harmful effects.[87] The characteristic clinical and radiological picture, supported by a negative Mantoux test and demonstration of noncaseating granulomas in transbronchial lung biopsy specimens, is fairly diagnostic of sarcoidosis.

The high-resolution Computed Tomographic (CT) scan has made it possible to diagnose and classify the idiopathic interstitial pneumonias. However, the recognition of several of the ILDs especially those of infectious origin, some of the IIPs, such as the organizing pneumonias and vasculitides, which require additional immunological tests and/or histological evidence for confirmation and, staging as well as for exclusion of alternate diagnoses remains somewhat unsatisfactory.[88,89] Transbronchial lung biopsy is fairly diagnostic in diseases such as sarcoidosis. One requires a transthoracic (thoracoscopic) or open-lung biopsy to reach a conclusive diagnosis for other conditions. It is quite likely that a large number of these patients are missed in India in the absence of a wider availability of some of the high-end diagnostic facilities.

Neoplastic Disorders

Respiratory malignancies, especially the lung cancer, have definitely increased in prevalence largely due to the widespread habit of tobacco smoking and exposure to environmental carcinogens.[90-93] Lung cancer occurrence in India has now overtaken the incidence of oropharyngeal cancer, which was earlier the most common form.[92] Lung cancer in India is shown to affect people of a relatively lower median age than that in the West. A significantly higher number of nonsmoker individuals are also affected. Passive exposure to environmental tobacco smoke is an important identifiable cause of lung cancer amongst nonsmoking spouses.[94] Atmospheric, environmental and occupational exposures are the other likely causes.[95] The grave threat from occupational asbestos has been listed earlier in this chapter.[78,79] Indoor radon exposure is another important cause. Unfortunately, the exposure information in India on most of these carcinogens amongst the general public, as well as the specific populations is highly unsatisfactory.

The epidemiology of lung cancer in India has not really changed over the past three decades. Perhaps, there has been no change in the smoking pattern of the population.[96] One can hope that recent implementation of tobacco-control policy by the Government of India may change the scene in the future. The epidemiology of lung cancer in India has not really changed over the past three years. Perhaps, there had been no change in the smoking pattern of the population.[96] One can hope that the recent implementation of tobacco-control policy by the Government of India may change the scene in the future. The management modalities, however remain limited partly because of the overall inadequacy of treatment of lung cancer and partly because of the scarcity of dedicated thoracic surgical and radiotherapy centers.[97] Most of the patients have advanced and nonoperable disease when first diagnosed. Surgical options for treatment at present are not very optimistic. Chemotherapy, widely employed for treatment is costly and unaffordable by most patients. The cost benefit ratio for most patients is not encouraging. Presently, primary prevention by tobacco cessation and control remains the most useful strategy to reduce the disease burden.

FUTURE SCENE OF PULMONARY MEDICINE IN INDIA

Pulmonary medicine, which developed as a superspeciality of medicine has now diversified to include several other subspecialities. Consequently, the spectrum and the scope have enormously expanded. As earlier discussed, the problems of tuberculosis, pneumonias and other respiratory infections will continue to constitute the major acute burden. On the other hand, respiratory allergies, such as asthma, COPD, environmental and occupational disorders, ILDs and lung cancer are likely to significantly increase over the next few decades. The introduction of endoscopic and image-guided procedures and interventions through bronchoendoscopy, thoracoscopy and mediastinoscopy, which have already improved our diagnostic and therapeutic skills, is bound to enlarge the boundaries of the speciality.

Pediatric and neonatal pulmonology are the other major pulmonary subspecialities in a rapid phase of development. Similarly, the increase in lifespan over the past few decades has widened the scope of geriatric-pulmonology. Pulmonary rehabilitation, palliative and end-of-life care are some of the resultant issues, which are rapidly emerging. There are several other groups of diseases and problems with the overlapping areas of interest with general medicine and other super or subspecialities. Some of these areas are still evolving in the developing countries. Occupational, industrial and rehabilitation medicine, sleep medicine, cardiopulmonary-medicine, diving, aviation, space and high altitude, trauma and disaster medicine are other important fields of health care, where pulmonary clinicians and scientists have a major share to contribute.

The most significant change in the scene has occurred with the introduction of respiratory critical care in the overall ambit of pulmonary practice. Critical care is a multispeciality discipline, but the respiratory physician plays the key role. Acute respiratory illnesses, severe pneumonias, sepsis, acute respiratory distress syndrome and pulmonary thromboembolism are some of the important problems encountered in all kinds of acute and chronic medicosurgical disorders, which require respiratory critical care. Malaria, tuberculosis, leptospirosis and acute viral syndromes, which may also present with acute respiratory distress syndrome are not uncommonly encountered in clinical practice.[98-100] Endotracheal intubation, bronchial hygiene, oxygen therapy and assisted respiratory support are some of the essential components of critical care for which the pulmonary intensivists are more actively required. Respiratory therapists and nurses now play a greater role in the disease management program.

Critical care has introduced a significant degree of skepticism and dilemma in the minds of health administrators and policy makers in India. Enormous inputs are required to provide costly care to a limited number of patients. The outcomes of critical care, especially in the presence of chronic diseases are also debatable. The ethical, moral, legal and social perspectives of critical care for the few, at the cost of a minimal level of care for all, have been debated and criticized.[101] This is especially so in the public health sector when the costs are borne by the governments. On the other hand, there is no denying the fact that the provision of the critical care makes all the difference between life and death for innumerable number of patients with catastrophic illnesses as well as for the victims of trauma and disasters. There is an enormous need and scope for the expansion of critical care services in India. The country has to evolve its own strategies and approaches to resolve the conflicting issues.

Lastly, there is a greater need for the development of both the clinical and the basic pulmonary sciences. Thoracic surgery in particular, is required to expand to cope up with the ever increasing list of indications. There is a wide gap in our knowledge and infrastructure to cope with the tremendous disease-magnitude. Although the scientific facts related to disease and management, are universal and globally applicable, the local problems are required to be handled with local perspectives. It is crucial to define the issues and find out their solutions through augmented efforts and inputs in research and development.

Practical Approach to Lung Health

Salah-Eddine Ottmani

INTRODUCTION

The Practical Approach to Lung Health (PAL) was initiated by the World Health Organization (WHO) in 1998.[1] It is a patient-centered approach to improve the quality of diagnosis and treatment of common respiratory illnesses in Primary Health Care (PHC) settings. It seeks to standardize service delivery through the development and implementation of clinical guidelines and managerial support within the district health system. It is intended to coordinate among different levels of health care and between Tuberculosis (TB) control and general health services.

The Practical Approach to Lung Health is included in the Stop TB Strategy developed by WHO and the Global Stop TB Partnership to control TB.[2] In this framework, PAL is assumed to contribute to strengthening health systems while addressing the quality of the management of patients with respiratory conditions, among whom TB cases should be identified. It also defines how the process of this management should be adapted to the health resources and infrastructure.[3,4] This is why PAL aims at improving the following:

- The quality of care in patients who seek attention for respiratory symptoms in PHC settings
- The efficiency of respiratory service delivery within health systems with a focus on the district health system.

This chapter describes the rationale behind the development of the PAL strategy, highlights its objectives, explains its components and why it should be adapted to the specific country health environment, specifies the successive steps needed to develop and implement PAL, reports the first country experiences in PAL development, and implementation and outlines its potential impacts.

DEMAND OF CARE FOR AND MANAGEMENT OF RESPIRATORY PATIENTS

The demand for respiratory care is common in PHC settings. Patients who seek care for respiratory symptoms account for up to one third among patients aged 5 years and more who attend PHC facilities for any reason.[5-8] Most of the surveys have reported that among respiratory conditions encountered in PHC, 60 to 90% are associated with Acute Respiratory Infections (ARI) while TB accounts for a very small proportion, most often less than 2%.[5-11]

In most developing countries, there are often clear guidelines on how to manage, in PHC, a TB patient irrespective of her/his age and children below five years of age with ARIs. However, for non-TB patients who account for more than 98% of respiratory patients aged 5 years and over, there are no clear indications on how to manage. Respiratory patients are usually managed on the basis of symptoms, in non-systematic and non-standardized manner, by PHC workers. As a result, the quality of diagnosis of respiratory diseases is often poor, the treatment prescriptions are often inappropriate and unnecessarily costly and there are no clearly defined criteria for referral. For instance, two studies carried out in PHC facilities in Jordan and Syria have shown that more than 85% of respiratory patients were prescribed antibiotics;[8,11] another study undertaken in Kyrgyzstan, reports that 40% of respiratory patients are referred from first level health facility to an upper health level.[7] It is clear that this contributes to wasting resources for the patients as well as for the health system.

The development and implementation of a comprehensive, standardized and integrated symptom-based strategy to manage respiratory patients in PHC is likely to improve the quality of care and, subsequently, create conditions resulting in improving the identification of TB cases. These principles are the key elements in the development of PAL.

OBJECTIVES OF THE PAL STRATEGY

The Practical Approach to Lung Health is an integrated and syndromic approach to manage respiratory patients aged 5 years and over. It focuses on priority respiratory illnesses encountered in PHC.

Clinical Objectives

The Practical Approach to Lung Health targets in priority to improve the quality of respiratory care services. Indeed, it aims at the following:

- Improving the quality of TB diagnosis in patients with sputum smear-negative microscopy, particularly in People Living With Human Immunodeficiency Virus (PLHIV)
- Enhancing TB screening in patients with a chronic respiratory condition
- Strengthening the quality of care for TB patients
- Ensuring TB treatment success
- Standardizing an appropriate management of ARIs
- Improving the management of respiratory infections in PLHIV
- Upgrading the quality of treatment of asthma attacks and Chronic Obstructive Pulmonary Disease (COPD) exacerbations
- Organizing and monitoring the long-term management of patients with Chronic Respiratory Diseases (CRD).

Managerial Objectives

These objectives focus on increasing the efficiency of the operations to implement PAL activities through

- Setting criteria for the request of laboratory tests, thorax radiography and other complementary tests
- Standardizing the drug treatment of respiratory diseases
- Promoting the essential drug lists of countries
- Establishing clear criteria for referral and counter-referral for respiratory patients within district health systems
- Defining the role of each health worker category in respiratory care management according to the health care level
- Defining planning parameters and contributing to rationalizing the management of health resources
- Monitoring and evaluating the performance of the health service delivery for respiratory conditions through the utilization of the existing Health Management Information System (HMIS) and TB control information system.

Economic Objectives

These are intended to decrease the cost of management procedures and to promote cost-effective health care interventions for respiratory illnesses by

- Reducing the managerial cost per respiratory patient while improving her/his quality of life
- Reducing the absenteeism associated with asthma and COPD
- Reducing the attendance at emergency room and intensive care unit by patients with CRD
- Increasing the number of respiratory patients managed in PHC settings while reducing hospital morbidity associated with respiratory diseases.

COMPONENTS OF THE PAL STRATEGY

In order to improve the quality of respiratory case management and the efficiency of health care services for respiratory illnesses, PAL includes two important components:

- Standardization of clinical care
- Coordination.

Standardization of Clinical Care

The standardization of respiratory care needs the elaboration of clinical guidelines. The process of PAL guidelines preparation needs to follow the national procedures to develop guidelines. The guidelines should be in line with the following:

- The international recommendations on the management of lower ARIs and pneumonia[12-16]
- TB management as specified by WHO[17]
- The management of asthma and COPD as recommended by international initiatives[18-20]
- The rules on drug prescription.[21]

The development of PAL guidelines should take into account the existing national guidelines, such as the National TB Program (NTP) guidelines, HIV/ Acquired Immuno Deficiency Syndrome (AIDS) guidelines, the Integrated Management of Adolescent and Adult Illness (IMAI) guidelines or other clinical guidelines. The PAL guidelines should clearly specify the categories of health workers who will use these guidelines and at which health care level and define the tasks that the latter will carry out. The main component of the PAL guideline is a section, which includes a clear description of the standardized clinical management of respiratory illnesses; this section specifies the clinical criteria for which respiratory patients should be referred or counter-referred. The drugs specified in the guideline should be as much as possible in line with the national essential drug list or with the national essential drug program.

The drugs and the equipment needed to carry out the tasks described in the PAL guidelines should be clearly identified in individualized sections. The process to monitor and evaluate PAL activities should be described; this process should use as much as possible the existing information systems such as the Health Management Information System (HMIS) and the NTP information system.

The PAL guidelines also include a component dealing with health education for patients. This should focus on these objectives:

- Ensuring that TB patients cooperate with directly supervised treatment and contacts are screened for TB
- Ensuring that asthma and COPD patients adhere well to self-medication
- Helping asthma patients to avoid asthma attack-triggering factors
- Advising all respiratory patients who smoke, to stop smoking
- Promoting prevention against tobacco use among respiratory patients.

The PAL guidelines should be developed in priority for health workers practicing in first level health facilities. The clinical approach described in this guideline should be patient-centered, symptom-based, integrated and standardized. The management should use a minimum number of signs and symptoms that are effective to determine the degree of severity, classify the disease and make the appropriate decision, namely:

- Urgent referral to the hospital for urgent management
- Referral for complementary investigations
- Investigation for TB diagnosis
- Treatment and observation at the health unit
- Specific home treatment
- Symptomatic home treatment.

A specific PAL guideline can be developed for the first referral level health facilities. This guideline is usually more disease-based with details on differential diagnosis. It includes three sections in function of the respiratory conditions usually encountered in:

- Emergency room
- Outpatients department of clinical medicine or TB and chest clinic
- Hospital ward

This guideline needs to clearly define the role of the first referral health level and standardize complementary investigation, including pulmonary function tests.

Furthermore, it should help health workers practicing at this level identify respiratory patients who need to be referred to the second referral health level for more specialized investigations or care; it also provides indications on when to counter-refer patients to first level health care network.

When these two guidelines are, both, adopted and developed in the same country, they should have well established connections.[21]

Coordination

Coordination in the PAL strategy refers to the identification and involvement of the key components of the health system in the organization and the efficiency of health care service delivery for respiratory illnesses. Country experience showed that these components are many and may vary among countries.

To be successful, coordination also needs to clearly define the involvement, in respiratory case management, of each health care provider category and of each health care level. This results in coordination between first level health facilities and referral facilities, contributing subsequently, to full integration of respiratory case management within the health system, particularly at district level.

The development and implementation of the PAL strategy also requires coordination with the following:

- National health resource planning
- NTP, HIV/AIDS program, IMAI initiatives, PHC services and the management of general health services for training, supervision, logistics and communication
- HMIS to monitor PAL activities
- The essential drugs program in order to make drugs available and affordable for respiratory patients.

ADAPTATION OF THE PAL STRATEGY

The Practical Approach to Lung Health must be adapted to the national health policies and resources. National health policies vary among countries in function of the health priorities, which depend on the national epidemiological challenges. For instance, in low income countries and in high HIV prevalence settings, infectious respiratory illnesses account for a higher proportion of the respiratory diseases burden than CRDs; this distribution tends to reverse with country income; in high income countries, CRDs represent the highest proportion of respiratory diseases' burden (Table 35.1). Therefore, in countries with epidemiological pre-transition, the control of tuberculosis and ARIs are likely to have preference over the need to improve case management for CRDs, while in settings with epidemiological transitional or post-transition, CRDs are likely to be considered as important health priorities.

The resources available within the health system widely differ among countries. These differences are related to various factors, such as:

- The number of health care levels
- The educational and training level of health staff
- The accessibility to laboratory facilities
- The availability of equipment, whether basic (e.g. functioning weighing scales, thermometers) or diagnostic (e.g. stethoscope, sphygmomanometer, peak flow meter, spirometer, X-ray) or therapeutic (nebulizers, sources of oxygen)
- The availability of a national essential drug program
- The existence of a scheme of health care cost coverage
- The accessibility to and affordability of certain drugs such as medications for inhalation use
- The accessibility to hospitalization
- The coverage of the health system by HMIS and NTP information system. For instance, comparison of Tables 35.2A and B highlights the similarities and differences between Peru and Syria with regard to the health resources available in their health care facility categories.

TABLE 35.1: Distribution, in percentage of DALYs, of respiratory diseases' burden in the population over 15 years of age by epidemiological profile and socioeconomic status of countries in 2000

Respiratory Conditions	*High HIV Prevalence Countries*	*Low Income Countries*	*Middle Income Countries*	*High Income Countries*
Acute respiratory diseases	70.8%	59.4%	32.4%	12.8%
Chronic respiratory diseases	16.0%	30.6%	58.0%	73.5%
Other respiratory diseases	13.2%	10.0%	9.6%	13.7%
Overall	100.0%	100.0%	100.0%	100.0%

STEPS TO INTRODUCE THE PAL STRATEGY IN COUNTRIES

To initiate PAL strategy in a country, a stepwise approach is required. This approach includes approximately 10 steps that are described in detail elsewhere.[22]

Promotion of the PAL Strategy within Country

To stimulate the political commitment of the national health authorities for PAL and encourage the involvement of the potential stakeholders in the future PAL activities, one document or more on PAL should be prepared and distributed.

This/these document(s) should include the main background data that help to understand the foundations of PAL strategy, its objectives, components and perspectives based on the WHO recommendations on PAL[1,3-5,22-24] and the countries' experiences in PAL development and implementation.[6-8,10,11,25-32] Seminars, workshops or meetings involving influential health authorities and key stakeholders may be organized in order to explain the concept of PAL strategy as well as its advantages and implications on strengthening TB control, PHC services and district health system. Participants in these meetings may issue recommendations to the national health authorities and/or relevant health institutions of the country to initiate the process of PAL development.

Political Commitment

As a second step, the Ministry of Health (MOH) should issue an official statement announcing that PAL development should be explored in pilot sites and its perspectives of implementation and impact should be assessed. This statement should be circulated among the relevant programs and departments within the MOH. An official memorandum requesting their support in developing PAL strategy should also be issued whenever needed. A focal point within the MOH should be designated in order to coordinate the introduction of PAL.

National Working Group (NWG) on PAL

The establishment of a NWG on PAL is crucial for initiating PAL and provides essential leadership for the subsequent steps.[22] The role of the NWG is not only to lead the initial PAL activities, but also to ensure the involvement of all the relevant stakeholders in implementing PAL.

The NWG should include members who represent various entities, such as NTP, PHC services, IMAI initiatives, HIV/AIDS and essential drug programs, drug procurement policy, HMIS and health sector reform departments, health care service planning, chest specialists from academic institutions, physicians and nurses practicing in PHC settings and at referral levels, health insurance funds, nongovernmental organizations operating in communities, cooperation agencies and others.

Assessment of Health Environment to Adapt PAL

This assessment should be carried out under the responsibility of the PAL focal point and the NWG. The assessment findings are crucial to adapt PAL development and implementation to National Health Policy and priorities as well as to the existing health infrastructure and resources. Moreover, the assessment should aim at identifying any existing funding or institutional mechanism, which can facilitate PAL implementation as well as any further resource, which can support the NWG tasks in developing PAL. This assessment should be based on various elements,[22] such as:

- The Public Health Sector Policies in relation to: budgetary priorities, programs' integration, health care services' management, planning and financial procedures, essential package of health services and contribution of external support to the health sector
- The process of decentralization and health sector reform
- The managerial organization of the ministry of health at central, regional and district levels
- The managerial activities to implement interventions such as training and supervision
- The level of demographic and epidemiologic transitions, as well as the burden of respiratory illnesses within the national health system
- The situations of TB and TB control, as well as the level of HIV burden in the general population and risk groups
- Populations covered by health care services, particularly PHC and by a health insurance system
- Resources available within the health system to manage respiratory conditions
- The organizations of the referral system and of HMIS
- The organization of respiratory disease management, such as the existence of management guidelines for TB, pneumonia, asthma, COPD or any respiratory condition or the existence of organized referral system for CRDs and others.

PAL Guideline Adaptation and Development

The guideline development is the key element to standardize respiratory care provision. PAL guidelines should be developed by the NWG. The existing country guidelines and/or WHO guidance can help in developing PAL guidelines for a country.[22,24,28,30,33] Other elements and documents should be considered in the development of the PAL guidelines, such as:

- The national procedures to prepare a guideline
- The NTP guideline
- The national policy on HIV/AIDS care and control
- The respiratory disease-based guidelines already developed in the country by the MOH and/or medical professional associations
- The international recommendations on the managements of lower ARIs/pneumonia, asthma, COPD and TB,[12-21,34] as well as on smoking cessation.[35,36]

The guideline for first level health facilities should be symptom-based with a clear connection with the guideline for referral level. The guidelines should:

- Refer to the respiratory illnesses considered as health priorities in the country
- Clearly specify the equipment and the essential drugs needed to manage the respiratory conditions targeted
- Clarify the referral process for respiratory patients between the first level health facilities and the upper health care level facilities
- Specify the routine information system to be used based on the existing HMIS and involving the NTP recording and reporting system.

Training Material Development for PAL

The training material should be developed by the NWG after the finalization of PAL guidelines. It should target the appropriate utilization of PAL guidelines by health care workers in their daily tasks. The training of health workers is organized through workshops.[22]

The training material includes the following:

- The PAL guidelines
- A simplified document explaining the basic concepts and rationale of the PAL strategy
- A participant module, which explains the training objectives and activities, presents clinical cases as problems to be solved in terms of management, and describes necessary communication skills; the problem-solving approach should cover all the components of PAL guidelines
- A facilitator module, which gives the expected answer(s) to each clinical case and exercise and refers to the relevant sections of the guidelines
- A workshop director module, which provides guidance in the administrative and logistic requirements to effectively conduct the workshop.

PAL Site-Piloting

The NWG should test PAL strategy in selected health facilities, easy to supervise with motivated health professionals who provide care services to communities important in size. Testing PAL may focus on assessing the perception, by the health workers, on the usefulness and the quality of PAL guidelines, as well as on evaluating whether the guidelines could be expected to be effective in producing the desired changes in outcomes. For this, the Appraisal of Guidelines Research and Evaluation in Europe (AGREE) Instrument[37] can be used.[26]

The site-piloting can be also undertaken in the framework of a feasibility test of PAL. The objectives of this test are to assess the impact, in the short term, of the implementation of PAL guidelines on the knowledge of the health care workers and on health care delivery to patients with respiratory symptoms in PHC settings. The test is carried out in three phases and involves 80 to 100 health professionals practicing in selected PHC facilities.[22] In the first phase, the management of respiratory patients by the PHC workers is assessed for five consecutive days before any training on PAL. This assessment provides baseline data. The second phase consists of the training of the same PHC workers on the PAL guideline using the training material developed by the NWG. In the third phase, the management of respiratory patients by the trained PHC workers is reassessed in the same conditions as the baseline study. The data collected in the first and third phases are compared and analyzed in order to show whether the health care services for respiratory patients are more rationalized by the use of the PAL strategy.[6-8,10,11]

Development of PAL Implementation and Expansion Plan

The plan to implement and scale up PAL activities can be established for specific regions, in a first phase, or for the whole country. It needs to be elaborated in close coordination with the NTP and the national PHC department and discussed with the other relevant stakeholders. The plan should specify the equipment needed for each health care level in line with the directives included in the national guidelines on PAL. It should also establish a training agenda for heath professionals practicing in first health care level and referral level, including emergency room. To this end, a core of trainers needs to be organized at national level and, whenever needed, at region level.

The plan should clearly identify the entity, which will be responsible for the training. In Kyrgyzstan, the national training agenda on PAL was carried out by the Kyrgyz State Medical Institute of Postgraduate and Continuous Medical Education.[31] In Egypt, El Salvador, Jordan and Morocco, a core of national trainers from NTPs, PHC services and medical schools was constituted; this core is in charge of the implementation of the training program on PAL through a network of trainers at regional level. In the Free State Province, South Africa, the TB nurse coordinators' network was used to train the primary care nurse practitioners.[29]

Mobilization of Funds for PAL Implementation and Expansion

After the development of the plan to implement and expand PAL, the national health authorities should explore the potential sources of funding to implement the activities identified in the plan.

Government may provide funds for all the components of the plan or financially support specific parts of the plan. In some circumstances, funds can be mobilized through the process of the health sector reform or from potential donors. In Chile, the plan of PAL expansion was fully financed by the Chilean government in the framework of the health sector reform. In Kyrgyzstan, training on PAL was financially supported through the ongoing health sector reform, but the equipment needed was funded by the Ministry of Foreign Affairs of Finland. In Morocco, the training was financially supported by WHO, while the equipment procurement was financed by the MOH. In some countries, such as Brazil, India and South Africa, PAL development and implementation has not been financially supported by federal funds, but by state or province funding.

Sources of funding should also be explored through bilateral and multilateral cooperation with donors involved in the development of health care services within the country. As PAL is a subcomponent of the Stop TB Strategy, the Global Fund Against HIV/AIDS, Tuberculosis and Malaria (Global Fund), has financially supported many countries to implement PAL in order to contribute to strengthening health systems. To date, approximately 35 countries have received funding for PAL from the Global Fund. The amount of funds provided by the Global Fund increased from 1.9 million US $ at the Round 6 to 13.9 million US$ at the Round 9.

PAL Implementation and Expansion

PAL implementation and expansion should be under the leadership of a clearly identified coordination unit within the MOH. This unit can be under the responsibility of the NTP or PHC department. Other ministerial departments can take the leadership to implement and expand PAL. However, PAL activities should be always implemented in close collaboration with the NTP and

PHC services. In Bolivia, El Salvador, Jordan, Morocco, Nepal and Syria, PAL expansion is under the responsibility of the NTP, while in Chile it is under the responsibility of the PHC Department and in Kyrgyzstan under the responsibility of the Department of Health Sector Reform. Once funds are available, the PAL unit should proceed to their budgeting in order to procure equipment and organize the training sessions.

When PAL activities are carried out within district health system, the PAL coordination unit should, in collaboration with NTP, PHC services and HMIS, implement the monitoring and supervision system and collect information on a routine basis in order to evaluate the performance of PAL activities.

RESULTS FROM COUNTRY EXPERIENCES

The number of countries with PAL activities have increased since 2002. To date, there are approximately 50 countries with some form of PAL activities. Among them, 12 are at the phase of expansion; Chile and Kyrgyzstan have succeeded to implement PAL in all PHC facilities of the public sector. Many countries are still at the phases of the development of PAL guideline and training material or site-piloting. In other countries, even though the phase of PAL site-piloting was successfully carried out and the plan to expand PAL activities established, the funds needed to implement this plan have not been yet mobilized.

The available results have mainly come from the feasibility tests and operation research carried out in countries. The routine information system for PAL activities established in countries where PAL expansion is progressing has provided, to date, very few data. However, the available results suggest that the PAL strategy has an impact on respiratory case management.

PAL and the Integration of Respiratory Case Management in PHC Settings

The feasibility tests carried out in pilot sites showed that after training of PHC workers on PAL, the proportion of respiratory patients referred from first level health facilities to referral level either for hospitalization or for further clinical investigation decreased by 16% in Guinea, 26% in Jordan and approximately one-third in Bolivia and Kyrgyzstan.[6,7] These findings suggest that PAL strategy may facilitate the integration of respiratory case management within PHC services. However, these results were not confirmed in the feasibility tests of PAL carried out in Syria and Tunisia where the proportion of respiratory patients referred from first level health facilities was already low at the baseline assessment.[8]

A randomly controlled trial, carried out in South Africa, showed that the referral of respiratory patients who need urgent referral from PHC facilities improved with PAL.[25]

PAL and TB Control

Findings from the feasibility tests and operational research carried out in Algeria, South Africa, Syria and Tunisia suggest that training on PAL tends to increase the proportion of respiratory patients in whom sputum smear microscopy is requested.[8,10,25] Data from South Africa showed that PAL guideline, used by nurses practicing at outreach level, significantly contributes to accurately identifying patients with the high probability of carrying active TB.[28] Results of the feasibility tests undertaken in Bolivia, Syria and Tunisia highlighted that PHC workers trained on PAL proceed to a better selection of TB suspects among respiratory patients.[6,8] In contrast, these findings were not observed in the feasibility test carried out in Kyrgyzstan.[7]

Results showing an impact on TB detection are still not yet widely available. The randomly controlled trial carried out in South Africa showed that the probability of detecting TB among patients with respiratory symptoms increased by 72% in PHC centers with nurses trained on PAL in comparison to PHC centers with nontrained nurses,[25] while the feasibility test undertaken in Algeria reported that the proportion of TB cases identified among respiratory patients increased by 120% after training of PHC workers on PAL.[10] The feasibility tests carried out so far in the other countries have failed to yield such results on TB detection. The approach used to carry out a feasibility test is probably not the appropriate method to show such impact, given that the study populations involved are often too small to detect small proportions of TB cases among respiratory patients.

PAL implementation is far advanced in Chile and Morocco. PAL impact on TB detection is not visible in these two countries since both of them had a high TB case detection rate (more than 80%) before PAL implementation. However, this impact might be more significant in countries with a low TB detection rate. Data regarding PAL impact on TB case detection need to be collected on routine basis in countries where PAL is scaling up.

In countries with high detection rate, PAL may improve the quality of TB diagnosis. Indeed in Morocco where PAL services were initiated in 2002 and are presently available in 75% of the public PHC facilities, the routine information system on TB control showed an increase in the bacteriological confirmation of pulmonary TB: from 83% in 2001 to 87% in 2007. The effect of PAL on TB treatment outcome is very scarce. Only one study undertaken in South Africa reported a significantly higher treatment success rate in retreatment of TB patients.[32]

PAL and Drug Prescription

Country experiences in PAL implementation suggest that PAL is likely to decrease drug prescription, particularly at the expense of antibiotics and adjuvant drugs, and to increase the prescription of drugs for inhalation use. The feasibility tests carried out in Algeria, Bolivia, Jordan, Kyrgyzstan, Morocco, Syria and Tunisia[3,6-8,10,11] showed that, with PAL, the number of drugs prescribed per respiratory patient significantly decreased by 10 to 19% and the proportion of respiratory patients who were prescribed antibiotics, by 10 to 33%. Significant decrease in the prescription of adjuvant drugs, such as expectorants and vitamins was consistently observed with PAL in the country feasibility tests.[6-8,10,11]

The cluster randomized trial, involving PHC facilities in Nepal, reported that PAL guidelines' implementation significantly reduced the average prescription by six drugs for every 10 prescriptions and tended to increase the prescription of drugs from the essential drugs' list.[27] The data collected in the feasibility test carried out in Bolivia, Jordan, Kyrgyzstan, Syria and Tunisia highlighted that, after training on PAL, there was a significant decrease in prescription of bronchodilators and corticosteroids; however, among patients who received bronchodilator or corticosteroid prescription the proportion of those who were prescribed inhalers was significantly higher after training on PAL. In addition, data from Morocco highlighted a higher prescription of inhaled β2-agonists with PAL guideline while the randomly controlled trial carried out in South Africa[25] and the routine data collected in Chile[38] showed a significant increase in the prescription of corticosteroids for inhalation use in PHC facilities with PAL services.

PAL and Cost of Drugs Prescribed

Most of the data collected in the countries where PAL has been initiated, highlighted a decrease in the cost of drug prescription with PAL. The feasibility tests carried out in Algeria, Bolivia, Jordan, Kyrgyzstan, Morocco, Syria and Tunisia[3,6-8,10,11] reported a decrease by 8 to 32% in the average cost of drugs prescribed per patient after training of PHC workers on PAL. This decrease is most often associated with significant reductions in the average costs of the prescriptions of antibiotics and adjuvant drugs.[6-8,10,11] The data of some of these feasibility tests showed that after training on PAL there was a decrease, by 16 to 26%, in the average cost of antibiotic prescription among the respiratory patients who were prescribed antibiotics.[6-7,10]

Such findings suggest that PAL is likely to promote a cheaper antibiotic prescription. This can be explained by the fact that the utilization of the PAL guidelines developed in the countries involved the prescription of antibiotics specified in the national essential drug lists. Furthermore, the operational research study undertaken in Nepal reported that patients visiting PAL facilities, on an average, spent less on health care-related costs per respiratory episode, including expenses for drugs, fees and diagnosis tests, as well as on non-health care related costs.[39]

PAL and Quality of Life

PAL is expected to improve patients' symptoms and quality of life. The studies on these aspects are very scarce and difficult to undertake, given that PAL deals with a broad spectrum of respiratory disorders. However, a few findings have been reported from countries where PAL has been introduced. Indeed, a sample selected from the data collected on routine basis in the PAL sites in Chile shows that after one year of follow-up of 250 asthma patients, the number of hospitalizations and emergency room visits, as well as sleep disturbance and daily life limitations in these patients, have significantly decreased after PAL implementation.[38] The cluster randomized trial carried out in Nepal suggested that there was a greater effectiveness of treatment services provided in the PHC facilities with PAL in patients with difficult breathing with a nonchronic cough in comparison to PHC facilities with no PAL services.[39]

Using generic health-related quality-of-life measurements adapted to the local setting, the authors of this study showed that patients with a chronic cough treated in health facilities providing PAL services had better health-related quality of life outcomes than those who were treated in health facilities with no PAL services.[39]

PAL and Cost-Effectiveness

The cost-effectiveness of PAL has not been yet fully studied; the data on this issue are very rare. However, a cluster randomized controlled trial carried out in South Africa, in which nurses were trained on PAL, using an educational outreach method, reported that PAL intervention increased TB case detection, as well as the proportion of respiratory patients appropriately managed; the cost generated was $68 more for each extra patient with TB detected and $15 more for each extra respiratory patient appropriately managed. The authors of this study concluded that the extra cost of increasing TB case detection was comparable to the usual cost for passive TB case detection. Moreover, the intervention increased cost-effectiveness by also improving the care of other conditions.[40]

In the cluster randomized trial undertaken in Nepal, the findings generated by mathematical modeling procedures suggested that PAL implementation is relatively cost-effective. Implementing PAL services at all first level public health facilities in Nepal would cost $111 per quality-adjusted life year gained compared with no PAL implementation. Using a threshold of $150 per quality-adjusted life year gained the probability for PAL to be cost-effective is 54%.[39]

CONCLUSION

PAL is a subcomponent of the Stop Strategy aiming at improving respiratory care in PHC setting while contributing to strengthening health system, particularly at district level.[2] Country experience suggests that PAL can contribute to improving TB case detection as well as the qualities of TB diagnosis and TB care. It provides an essential and integrated health care package in order to address the challenging burden of respiratory illnesses in PHC setting. Country experience suggests that PAL upgrades the skills of PHC workers. Therefore, PAL is likely to strengthen PHC services and increase their utilization by meeting the needs of patients with respiratory symptoms.

PAL is believed to facilitate planning of health resources within the district health system, since standard case management should clearly define the training needs, equipment, drugs and other supplies for the first-level health facilities and the referral level. Data from countries indicate that PAL significantly improves drug prescription while decreasing drug prescription costs. Preliminary findings from Nepal and South Africa suggest that PAL may be cost-effective as a health intervention.

Most of the results of PAL implementation that have been reported, to date, mainly show a short-term impact of PAL, observed in the framework of feasibility tests or operational research studies. The outcomes of the long-term application are still unknown and need to be fully analyzed. It is expected that the appropriate application of PAL on routine basis will do the following:

- Increase the proportion of respiratory patients managed in PHC as a result of the improvement of the integration of respiratory care in PHC
- Decrease the proportion of respiratory cases in hospitals because of the improvement of respiratory care in PHC
- Improve the quality of the diagnosis of pulmonary TB among respiratory patients
- Decrease the number of asthma attacks and exacerbation of COPD particularly in emergency rooms and hospitals
- Reduce the cost of respiratory case management and improve the quality of life of respiratory patients particularly those with chronic respiratory conditions.

These characteristics should be documented in countries where PAL is in the process of expansion.

The WHO (India) and the Government of India have developed National guidelines for the management of CRD (COPD and asthma) at primary and secondary levels of health care in accordance with the PAL strategy.[41] The PAL implementation is likely to follow soon.

Epidemiology of Pulmonary Tuberculosis

VK Chadha

INTRODUCTION

Tuberculosis (TB), among the ten leading causes of death worldwide, remains a major public health problem in many countries.[1] It is estimated that about the one-third of world's population is infected with tubercle bacilli.[2] The absolute incidence of all types of TB cases globally during the year 2008 was estimated at 9.4 million, at the rate of 139 per 100,000 population.[3] The worldwide point prevalence was 11.1 million at 164 cases per 100,000 population.[3] About 1.3 million people presumably died due to TB at the rate of 20 per 100,000 population.[3] Of the 199 countries, 80% of the global incident cases each year are concentrated in 22 High-Burden-Countries (HBCs).[3]

Organized TB control programs were introduced from the middle of the 20th century. The very first scientific, community-based effort was implemented all over India from the year 1962 in the form of National Tuberculosis Program (NTP). However, TB continued to be a major public health menace especially in most developing countries due to the ineffective implementation of planned strategies, primarily attributed to managerial deficiencies and lack of sufficient resources. In recent years, new found political will has motivated health providers to consolidate managerial skills to bring in focus on target-oriented results. To give further impetus on control, Directly Observed Treatment Short-Course (DOTS) which is an internationally recommended TB control strategy, was introduced worldwide during 1990s. DOTS has since been further energized by enlarging its scope and content by the Stop TB strategy, which emphasizes on addressing the coepidemic of TB-Human Immunodeficiency Virus (HIV) and Multidrug-Resistant Tuberculosis (MDR-TB), needs of the poor, empowering people through Advocacy, Communication and Social Mobilization (ACSM) activities, engaging private providers and Nongovernmental Organizations (NGOs).[4]

The ultimate aim of TB control programs is to reduce the incidence of TB in the community. The Millennium Development Goals (MDGs) of the United Nations provide a framework for evaluating the progress in TB control. The principle target of MDGs for TB control is to ensure that incidence rates of TB decline globally by 2015. This is envisioned in the annual targets of case detection of new smear-positive PTB cases under DOTS strategy and their treatment success, set earlier by the World Health Assembly in 1991 and also adopted by Stop TB Partnership[5] (Table 36.1). The supplementary targets, are to halve the prevalence of TB and TB mortality rates by 2015, keeping 1990 as the base year (Table 36.1). These targets were based on a resolution at a meeting of the Group of Eight (G8) industrialized countries held in Okinawa, Japan in the year 2000. The year of 1990 was chosen as the baseline, since it was in this year that TB was declared a "global emergency" by the World Health Organization (WHO) leading to conceptualization of DOTS strategy. Stop TB Strategy further aims for the elimination of TB by 2050.

NATIONAL DYNAMICS OF TUBERCULOSIS

The study of "natural dynamics" aims to understand the basic or fundamental laws, which govern all events that take place between the tubercle bacilli and community

TABLE 36.1: Goals, targets and indicators for TB control

(a) Millennium development goal 6: Combat HIV/AIDS, malaria and other diseases	
Target 8	Have halted by 2015 and begun to reverse the incidence of malaria and other major diseases.
Indicator 23	Prevalence and death rates associated with tuberculosis.
Indicator 24	Proportion of tuberculosis cases detected and cured under DOTS (the internationally recommended strategy for TB control).
(b) Stop TB partnership targets	
By 2005	At least 70% of people with sputum smear-positive TB will be diagnosed (under the DOTS strategy), and at least 85% cured.
By 2015	The global burden of TB (per capita prevalence and death rates) will be reduced by 50% relative to 1990 levels.
By 2050	The global incidence of active TB will be less than 1 case per million population per year.

under natural conditions, where active interference in the form of organized control measures is not in place.

The transmission of tubercle bacilli happens through the air when people with active tuberculosis cough or sneeze. For infection# with *M. tuberculosis* to take place, an infectious patient must be able to produce airborne infectious droplet nuclei$ containing tubercle bacilli. Therefore, only cases of pulmonary TB can transmit infection. Majority of the transmission in a community happens from sputum smear-positive cases of pulmonary TB and smear-negative cases are only one-fifth as infectious as the smear-positive cases.[6] On exposure to an infectious TB case, certain factors determine the risk of infection among the exposed susceptible individuals. Once infection occurs, the probabilities of the infected individual to develop TB disease and death due to the disease depend upon a multitude of factors. Thus, there are four stages in the natural course of TB in an individual—exposure, infection, disease and death.

Exposure to Tuberculous Infection

Exposure is said to have taken place when an infectious case of TB and a susceptible person share the same air space where complete air exchange has not taken place between the visits of the two persons. Most transmission of infection occurs in confined spaces because airborne droplets are dispersed rapidly reducing the numbers of droplets per unit volume of air outdoors. Further, the bacilli are killed rapidly due to sunlight and drying. Nevertheless, transmission can also take place outdoors depending on case-contact proximity, when the case coughs directly on the mouth of the other person or talks in very close proximity. It has been estimated that five minutes of loud talk is equivalent to one forceful cough.

The risk of exposure primarily depends upon the incidence rate of cases in the community, the average duration of their infectiousness and the intensity of contact between cases and the susceptible individuals. The risk of exposure is also dependent upon the duration of infectiousness of the case. An untreated case stays infectious for a longer period than the one diagnosed and treated well in time.[7] Given the average delay between the onset of disease and diagnosis, a particular case has the potential to infect about 30 to 40% of her/his contacts before diagnosis.It implies that the proportion of contacts that acquire infection can be reduced by reducing the delay in diagnosis. This underlines the importance of pro-activism of diagnostic and treatment services in drastically reducing the transmission of infection in the community.

Infection transmission also depends on the average number of susceptible individuals that come in contact with a given case. A case in a household with larger family size will expose more persons than in a family of small size. For the same reason, the average number of persons who get exposed to a single case is considerably higher in urban than rural areas due to higher population density.

Infection with Tubercle Bacilli

Once exposed, the risk of becoming infected depends on the size of infectious droplet nuclei produced by the patient on coughing or sneezing and their density in the air. Droplets larger than 10 Microns (μ) in size settle to the ground rapidly whereas smaller droplets remain buoyant for a prolonged period of time. Even if inhaled, almost all droplets larger than 10 μ and the majority between 5 and 9 μ get trapped in the upper respiratory tract. Therefore, only the droplets of less than 5 μ have the potential to establish infection.[8] On an average, an untreated smear-positive case infects about 7–10 persons a year.[9] The average duration of an untreated smear-positive case is about 2 years beyond which either natural cure or death occurs.[10] Therefore, about 20 susceptible

---

#*Infection implies that the organism after introduction is able to establish itself in the body with the potential of either multiplication or development.*

$*The droplets, which contain one or more bacilli and are buoyant in air are called “droplet nuclei”.*

individuals would be infected by each smear-positive case, about 10% of whom would develop TB during their lifetime.[11] Therefore, the numbers of TB cases emerging in the community keep doubling over the course of one human generation, in the absence of control interventions.

TB cases who smoke are likely to associate their symptoms to their smoking habit and postpone taking remedial measures. This results in longer delay to initiate anti-TB treatment. The rates of success with anti-TB treatment have also been found to be poorer among smokers with higher rates of relapse of TB disease and death.[12] These factors along with increased frequency of coughing lead to the higher risk of infection among contacts of such cases. Given the mode of transmission, covering the mouth and nose during coughing and sneezing reduces the number of infectious droplets. However, wearing surgical masks by the exposed is not an efficient method of preventing transmission since these masks are not effective in filtering particles less than 5 μ and do not provide a tight seal around the mouth.[13,14]

Tuberculosis Disease

Given that the bacillus has established itself in the human body, numerous hosts related factors determine the risk of infection breaking down into disease. Most of the infected persons may never manifest with TB disease. The risk of developing TB largely depends upon the competency of immune system. The bacilli remain dormant in the body and may cause disease many years later when there is a decline in host immunity.

Factors Which Increase the Risk of Progression to TB Disease

The risk of breakdown and developing disease is very high during the first year following infection. While, the lifetime risk of a newly infected young child to develop TB is about 10%, half of this risk falls within the first 5 years of infection.[11] Therefore, 5 years has been arbitrarily chosen as the cut off point to demarcate primary TB from post-primary TB. In general, the younger the age of primary infection, the higher the risk of primary TB.[11] This also provides the basis for advocating chemoprophylaxis for young child contacts of TB cases.

Even though, the individual risk of developing TB is highest among the recently infected,[15,16] majority of the disease incidence is contributed by the remotely (more than 5 years) infected people. This is because the total numbers of remotely infected people are many times more than the recently infected.

The transmission of *M. tuberculosis* from man-to-man is more efficient than other mycobacteria. The risk of disease following infection with *M. tuberculosis* has also been found to be substantially higher when compared with infection with other mycobacteria like *M. bovis*.[17] Similarly, certain strains of *M. tuberculosis* are more virulent in causing disease.[18,19]

Significant differences in TB incidence by age and sex are largely attributed to differences in the risk of exposure. Community-based surveys generally reveal increasing trends in the incidence of pulmonary TB with age, which is partly due to increase in the prevalence of infection with age.[20, 21]

Incidence rates are generally two to four times higher in males compared to females.[20,21] However, given the same level of exposure to infectious cases, the risk of developing TB following infection has been observed to be higher among females especially in early adulthood period.[11,22] Differences in incidence between races are largely due to differences in the prevalence of infection. Also, the risk of disease following infection is significantly higher in virgin population, i.e. groups that have not been previously exposed to contact with TB cases.

A proportion of cases get naturally cured even without treatment. In a longitudinal study carried by the National Tuberculosis Institute, Bengaluru (NTI), during early 1960s, about 31% of smear-positive cases with X-ray shadows suggestive of TB had become culture negative after 1.5 years.[23] However, a higher risk of recurrence of TB in such naturally cured patients has been demonstrated in some studies.[24]

Smoking is one of the major risk factors inviting TB infection and disease.[12,25] Smoking has also been found to be related to severity of TB disease. A high prevalence of smoking in the economically most productive age group, which also bears most of the TB burden highlights its public health importance. Alcohol consumption has also been observed in a few studies to increase the risk of TB disease.[26] The risk is compounded in the presence of both smoking and alcohol.[12] HIV infection imposes a high risk of TB among people infected with HIV, as well as *M. tuberculosis*. High prevalence of HIV infection in certain population groups further increases the risk.[27]

About 15% of total incidence cases of TB and one-fourth of TB deaths worldwide in the year 2008 were estimated to be among HIV positive persons.[27] Similarly, one-fourth of the persons who died with HIV infection were also suffering from TB.[27]

Other Medical Conditions

Diabetes Mellitus (DM) is associated with an increased risk of TB, as demonstrated by a recent meta-analysis.[28] Persons with silicosis are at a significantly high risk of developing TB. A relative risk* of 2.8 was observed among men suffering from silicosis compared to those without silicosis in a prospective cohort study among gold miners in South Africa.[29] People with lower biomass index generally have a higher risk of TB.[30] The incidence of TB has been demonstrated to increase during the periods of food shortage implying the role of under-nutrition as a risk factor for TB. Certain malignancies have been identified to be associated with increased morbidity due to TB.[31]

Social Conditions

Poor socioeconomic conditions are associated with higher incidence of TB.[32, 33] There is higher level of infection transmission due to poor living conditions. In addition, poor nutritional levels enhance the risk of contracting TB. Homeless people experience a particularly high risk of both TB and HIV.[34]

Death Due to TB

Reduction in the risk of death from TB is dependent on the timely diagnosis and treatment. From public health point of view, pulmonary TB accounts for a majority of the TB deaths. The case fatality rates are much higher among smear-positive cases when compared to smear-negative cases.[35,36] If untreated, about one-third of patients with smear-positive pulmonary TB have been observed to die within one year of diagnosis.[37] About two-thirds die within five years. Inefficient case finding program, delay in diagnosis and poor quality of treatment not only increase the TB mortality, but also contribute to unchecked transmission of infection in the community.

THE EPIDEMIC CURVE OF TB

Temporal epidemic curves depict the time trends of morbidity and mortality of communicable diseases, in given communities. They usually show an ascending and a descending limb separated by a peak or an extended peak, which almost looks like a plateau (Fig. 36.1). The ascending limb of the curve called the "Epidemic Phase" represents the phase of rapid spread and increasing incidence with time. The peak/plateau aspect denotes the "Transitional Phase" when the disease incidence stabilizes. The descending limb represents the "Phase of decline". The time span of this phase is much longer than the epidemic phase since the rate of decline in disease incidence is much lower than the rate of increase during the epidemic phase. Thus, the ascending limb is steeper and shorter than the decelerating descending limb. The declining phase is often followed by a "Low Endemic Phase" when the cases continue to emerge at lower and lower incidence rates for varying periods of time. In the case of acute diseases, the duration of an epidemic curve is usually a few days, weeks or even months. In case of TB, under natural conditions without interference of control measures, the epidemic curve spans a century or more and is therefore called "Secular Curve".[38]

TB epidemic starts when infection is sown for the first time in a virgin community hitherto unexposed to TB infection. At the beginning, spread of infection is rapid and almost everybody gets infected. Most infected individuals develop disease since a large proportion of population is susceptible due to lack of immunity. Case Fatality Rates (CFRs) are high since most of the diseased die due to poor host resistance. Thus, there are high rates of morbidity and mortality. The steepness of the ascending limb is determined by the speed of spread, which depends upon the number of contacts per case per unit of time. The disease is common across all age-groups, childhood TB is common. During the early period of this

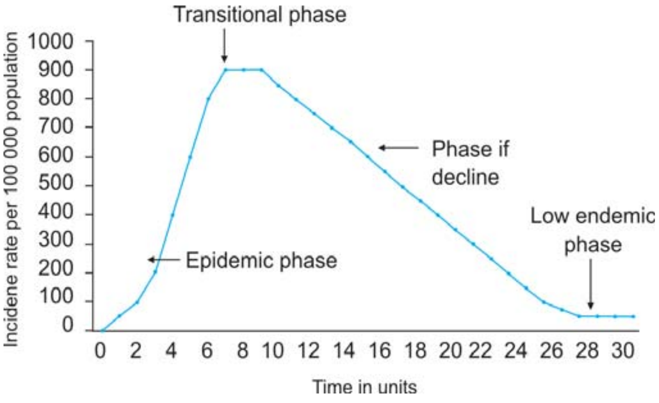

Fig. 36.1: A hypothetical epidemical curve

Note: The curve is imaginary. Incidence rates presented here cannot be extrapolated to any disease in a given community and depend upon local conditions taking different time periods for each phase

---

**Relative risk is the ratio of incidence of disease in persons exposed to a known risk factor to the incidence among the unexposed, over a given time period.*

phase, the disease is more concentrated in urban areas, increase in urbanization speeds up the epidemic. As the wave advances, infection and disease spread to rural areas. The disease is more of exudative and disseminative type.

During the transitional phase, incidence rates are still high, but remain stable over years without any significant increase. Morbidity and mortality are highest in middle ages. The disease is of mixed type, tending to become chronic and less generalized. Mortality diminishes slightly. During the phase of decline, prevalence of infection decelerates and TB incidence rates decline naturally. Because, the rate of decline is slower than the rate of increase during the epidemic phase, the phase of decline lasts for a much longer duration than the epidemic phase. The disease is more of localized variety resulting in an increase in the proportion of cases with cavitations. Even though the transmission rates continue to be high, there comes a moment when the numbers of susceptible contacts begin to decline due to the higher levels of resistance than before. The age at first infection gets shifted to adolescence and adulthood. Thus childhood TB becomes less common in the terms of absolute numbers and as a proportion of total cases. Majority of the disease gets localized to older age group, and the disease rates are similar in urban and rural areas. Case fatality and mortality rates decline in the community.

With time, the number of susceptible contacts is reduced to an extent that TB ceases as a public health problem. However, the descending limb of the epidemic curve does not touch the baseline and continues in the same mode indefinitely. This underlies the difficulty in eradication and the disease continues as a low endemic for prolonged periods of time. In primitive societies where there were limited transportation facilities, the epidemic wave of TB might run its course on a local scale. In countries with large population, different geographical areas may simultaneously experience different phases of the epidemic, depending upon the period of its introduction. Communities may also experience temporary fluctuations like in the case of social upheavals, wars and emergence of new risk factors. In modern times, immigration from high prevalence countries has lead to temporary upheavals in the "Phase of decline" in many developed countries.

The duration of each of the limbs of the secular curve of TB can be reduced by effective control programs.

METHODS TO MEASURE EPIDEMIOLOGY OF TB AND ITS TRENDS

The study of epidemiological situation of any disease provides insight into the disease burden shared by the community. Such information is vital for planning control strategies by harnessing required resources for their implementation. It is also imperative to measure the changes in incidence and prevalence of TB disease and mortality in order to monitor the epidemiological trends of the disease and the impact of control measures.

Measuring Prevalence of TB Disease

Prevalence is defined as the proportion of people suffering from TB disease at a given point of time, commonly expressed as a proportion per 100,000 population. Prevalence is the product of incidence and duration of illness. A good chemotherapy program reduces the average duration of illness. Therefore, in the presence of an efficient TB control program, the prevalence of disease declines more rapidly. Incidence takes longer to decline since new cases continue to emerge from amongst the pool of already infected people. Prevalence is generally estimated directly by community based cross-sectional surveys. Indirect estimates can also be made by using the above equation, provided reliable estimates of incidence and duration are available.

Surveys to estimate the prevalence of Pulmonary Tuberculosis (PTB) involve the following steps:

i. *Sampling:* Selecting a representative sample of the population by using appropriate statistical techniques of sample size estimation and the sampling process[β].
ii. *Screening:* To identify the individuals likely to suffer from TB, in the study population, one or both of the following screening tools are used: (a) Mass Miniature Radiography (MMR) of the chest, (b) personal interview to elicit the presence of one or more of the following pulmonary symptoms:
    - Persistent cough for $\geq$ two weeks
    - Fever for $\geq$ one month
    - Chest pain for $\geq$ one month
    - Hemoptysis: At least one episode during the last six months.

    Ideally, radiography, as well as symptom elicitation should both be used for screening. Radiography of

[β] *The sample size of about 1,80,000 is required to estimate prevalence within 15% of the true value for a cluster sampling design, if the expected prevalence is about 200 per 100,000 population. A similar sample size would be required if the objective is to estimate trends between two surveys five years apart with 90% power at 5% level of significance, expecting the prevalence as above at the first survey and change in prevalence at the rate of 5% per year. Much higher sample sizes would be required for more precise estimates of prevalence at any of the surveys.*

the chest has a higher sensitivity[Ω] than symptom screening for detecting active TB, but its application is cumbersome; whereas in symptomatic screening, which has lower sensitivity, there is likelihood of missing mildly symptomatic or asymptomatic cases.

iii. *Procedures to identify individuals for sputum examination:* X-ray films are read independently by two readers having vast experience in reading MMR films. Each independent reader classifies the X-ray films into one of the three categories—normal, nontuberculous lesion, tuberculous lesion. Individuals found to have abnormal shadow (tuberculous/nontuberculous), by any of the two independent readers are eligible for sputum collection. Similarly, individuals suffering from one or more of the symptoms are eligible for sputum examination.

iv. *Collecting sputum specimen:* Two sputum specimens (one spot and one overnight) are collected from each eligible individual.

v. *Bacteriological examination:* The sputum specimens are subjected to both smear microscopy, as well as culture for Acid-fast Bacilli (AFB).

vi. *Estimating prevalence:* Analysis is undertaken to estimate prevalence and the confidence intervals while taking into account the sampling strategy.

It is extremely important to estimate prevalence of bacteriologically positive PTB[©] efficiently because these cases are responsible for spreading infection in the community. For estimating prevalence of radiologically active PTB, those individuals whose X-ray films are labeled normal by both the independent readers are considered as such. In case of disagreement between the two readers, the film is referred to an umpire reader. Any individual with a lesion classified as tuberculous in nature, by at least two of the three readers is considered to suffer from radiologically active PTB. Often, there is a tendency to over estimate the prevalence of abacillary[μ] PTB, due to low specificity of chest X-ray. Some of the strengths and limitations of prevalence as an epidemiological indicator are summarized as under:

Strengths	*Limitations*
Prevalence changes quickly in response to efficient TB control activities	Large sample size needed to estimate prevalence
Reflects on the efficiency of case finding and treatment under TB control program	Prevalence surveys require huge resources in terms of skilled manpower, equipment, funds and organizational infrastructure
Surveys to estimate prevalence provide opportunity to include subsidiary objectives, for examples, to obtain information on risk factors, health seeking behavior. However, care should be taken so that the primary objective is not compromised.	A significant proportion (30 to 50%) of prevalent cases is missed if screening is based only on symptoms elicitation; if screening includes chest radiography, it is needed to transport radiology equipment to the field
	Not suitable to estimate the prevalence of childhood TB and extrapulmonary TB due to impracticability of required investigations under field conditions.

Measuring Incidence of TB Disease
